## STATUTORY DECLARATION

I hereby declare that I have authored this thesis independently, that I have not used other than the declared sources/resources, and that I have explicitly marked all material which has been quoted either literally or by content from the used sources.

Graz, 31.05.2013

Lukas Groschner

## EIDESSTATTLICHE ERKLÄRUNG

Ich erkläre an Eides statt, dass ich die vorliegende Arbeit selbstständig und ohne fremde Hilfe verfasst, andere als die angegebenen Quellen nicht verwendet, und die den benutzten Quellen wörtlich oder inhaltlich entnommenen Stellen als solche kenntlich gemacht habe.

Graz, 31.05.2013

Lukas Groschner

## ACKNOWLEDGEMENTS

I would like to express my gratitude to all those people who have contributed to this work in various different aspects and who have inspired me throughout my studies. Especially I would like to thank

...Wolfgang Graier, who is probably the most enthusiastic supervisor a young scientist could wish for and who taught me how important it is to love what you do. Thank you for your trust, inspiration and the freedom you gave me. ...Roland Malli, who was a seemingly endless fountain of clever and unconventional ideas throughout my studies.

...Rizwan, whom it was a great pleasure to work and share a project with, who had the patience to answer all my questions at any time of day or night, and with whom I hope to have plenty fruitful collaborations in not too distant future. ...Patrik Rorsman for inviting me to Oxford and letting me thrive on his unprecedented expertise in islet cell electrophysiology. ...Josephine Forbes and Melinda Coughlan for introducing me to the field of mitochondrial research. ...Vi for being both the best teacher and friend on the southern hemisphere. ...René for being the knight in shining armor he actually is, although he might not be aware of it. ...Elisa for introducing me to confocal  $\text{Ca}^{2+}$  imaging. ...Quan and Liang for teaching me how to isolate pancreatic islets. ...Sonja for spreading serenity throughout the lab. ...Claire, Markus, Jadoon, Neel, András, Warisara, Therese, Corina, Sasha, Sandra, Felix, Christiane, Nicole, Anna, Flo, Simone, Jan and Lissi for their help and hard work.

...my Mother and my Father for inspiring discussions, constructive criticism and their continuous unwavering support.

...Eva, whom I share everything with. Thank you for your confidence, your immeasurable help and endless patience.

This work was supported by a Student Research Fellowship of the Medical University of Graz.

## ABSTRACT

Pancreatic  $\beta$ -cells are the only cells capable of lowering blood glucose by secreting insulin. The  $\beta$ -cell continuously adjusts its secretory activity to substrate availability in order to keep blood glucose levels within the physiological range – a process referred to as metabolism-secretion coupling. Glucose is readily taken up by the  $\beta$ -cell and broken down into intermediates that fuel oxidative metabolism inside the mitochondria to generate ATP. The resulting increase in the ATP/ADP ratio causes closure of plasma membrane  $K_{ATP}$ -channels, thereby depolarizing the cell and triggering the opening of voltage-gated  $Ca^{2+}$  channels. Consequential oscillations of cytosolic  $Ca^{2+}$  not only mediate the exocytosis of insulin granules, but are also relayed to other subcellular compartments including the mitochondria, where  $Ca^{2+}$  might act to accelerate mitochondrial metabolism in response to nutrient stimulation. The aim of this study was to investigate the role of two proteins involved in the uptake of  $Ca^{2+}$  by the mitochondria, mitochondrial  $Ca^{2+}$  uptake 1 (MICU1) and mitochondrial  $Ca^{2+}$  uniporter (MCU), in metabolism-secretion coupling of the pancreatic  $\beta$ -cell.

Employing an RNAi-mediated gene silencing strategy, I could selectively suppress the expression of MICU1 and MCU in INS-1 832/13 clonal pancreatic  $\beta$ -cells. Silencing of MICU1 and MCU significantly reduced mitochondrial  $Ca^{2+}$  signals after stimulation with glucose. Cells deficient of MICU1 or MCU also failed to sufficiently increase  $O_2$  consumption rates and cytosolic ATP levels in response to high glucose. Glucose-stimulated insulin secretion was reduced by 57.7 and 41.8 % in cells treated with siRNA targeted against MICU1 or MCU, respectively.

The presented data illustrate the fundamental role of MICU1 and MCU in the feed-forward mechanism that guarantees sustained insulin secretion and thereby identify the mitochondrial  $Ca^{2+}$  uptake machinery as a promising therapeutic target for type 2 diabetes mellitus.

## ZUSAMMENFASSUNG

Die Funktion der  $\beta$ -Zellen des Pancreas besteht darin, den Blutzuckerspiegel durch die Sekretion von Insulin zu senken. Zu diesem Zweck muss die  $\beta$ -Zelle ihre sekretorische Aktivität fortwährend an schwankende Glucosekonzentrationen anpassen – ein Prozess, der als Stoffwechsel–Sekretionskopplung bezeichnet wird. Glucose wird dabei von der  $\beta$ -Zelle aufgenommen und treibt über die Bildung von Pyruvat den oxidativen Stoffwechsel der Mitochondrien an. Der dadurch bedingte Anstieg des ATP/ADP-Verhältnisses führt zum Schließen von  $K_{ATP}$ -Kanälen in der Plasmamembran und so zur Depolarisation der Zelle. Über die Öffnung von spannungsabhängigen  $Ca^{2+}$ -Kanälen kommt es daraufhin zu zytosolischen  $Ca^{2+}$ -Oszillationen, die einerseits die Exozytose insulingefüllter Vesikel auslösen, andererseits aber auch prompt in andere Zellkompartimente, einschließlich der Mitochondrien, fortgeleitet werden. Über die Aktivierung  $Ca^{2+}$ -abhängiger Enzyme der mitochondrialen Matrix kommt es so zu einer zusätzlichen Verstärkung der ATP-Produktion und damit auch der Insulinsekretion.

Die vorliegende Arbeit hat zum Ziel, den Beitrag von MICU1 und MCU, zweier Proteine, die in die mitochondriale  $Ca^{2+}$ -Aufnahme involviert sind, zur Stoffwechsel-Sekretionskopplung der  $\beta$ -Zelle zu untersuchen. Unter Anwendung von RNAi-vermitteltem Gen-silencing konnte ich die Expression von MICU1 und MCU in INS-1 832/13 Zellen selektiv hemmen. Gen-Knockdown von MICU1, wie auch von MCU unterdrückte die Glucose-induzierten mitochondrialen  $Ca^{2+}$ -Signale und verminderte zugleich den Anstieg des zellulären  $O_2$ -Verbrauches, als auch der ATP-Synthese nach Stimulation mit Glucose. Die Behandlung mit siRNA gegen MICU1 oder MCU führte außerdem zum Abfall der Glucose-induzierten Insulinsekretion um 57,7 bzw. 41,8 %.

Diese Ergebnisse verdeutlichen die grundlegende Rolle von MICU1 und MCU im  $Ca^{2+}$ -vermittelten positiven Feedback-Mechanismus, der eine adäquate Insulinsekretion ermöglicht und definieren dadurch mögliche neue Therapieziele für eine Behandlung des Diabetes mellitus Typ 2.

# 1 INTRODUCTION

The pancreatic  $\beta$ -cell is a particularly exciting type of cell, not only because its membrane harbors voltage-gated ion channels, which by definition make it an electrically excitable cell, but especially because of its unique way of adjusting secretory activity to substrate availability. There are not many cell types that are capable of accomplishing similar tasks and most certainly no other type of cell can secrete insulin, the one and only blood glucose-lowering hormone (1). Depletion or dysfunction of  $\beta$ -cells is unavoidably linked to the development of diabetes mellitus, a disease currently affecting over 6.4 % of adults worldwide (2) and causing one death every seven seconds (3). Along with the prevalence of this disease, diabetes-associated healthcare costs are also increasing at an enormous speed, accounting already for 2 to 7 % of national healthcare expenses in Western Europe (4), hence, placing a growing burden on both individual patients and national economies.

In order to provide better insight into the pathophysiology of diabetes mellitus, a detailed understanding of the process of insulin secretion is of utmost importance and has thus turned the pancreatic  $\beta$ -cell into an attractive target for both basic and clinical research. In the 1960s it was found that metabolic substrates and intermediates other than glucose had a similar effect on insulin secretion and that inhibition of intracellular metabolism is sufficient to prevent insulin secretion even in the presence of glucose (5). These observations have led to the idea that glucose elicits insulin release through metabolism of the hexose within the  $\beta$ -cell rather than through interaction with a specific receptor, thus ruling out the concept of a surface bound “glucoreceptor”.

Since then, the exceptional way of adjusting insulin secretion to the availability of metabolic substrates, a process also referred to as “metabolism-secretion coupling”, has attracted a lot of attention. In essence, this is achieved by different  $K_{ATP}$  channel-dependent and -independent mechanisms (6, 7). The uptake of glucose by the  $\beta$ -cell through glucose transporter 1 in humans and 2 in rodents and its oxidative metabolism yields a rise in the cytosolic ATP/ADP ratio. This, in turn, decreases the  $K_{ATP}$  channel’s open probability (8,

9), thus reducing the  $\beta$ -cell's membrane potential and causing the opening of voltage-gated  $\text{Ca}^{2+}$  channels. Triggered by the influx of  $\text{Ca}^{2+}$ , insulin-filled vesicles subsequently release their cargo and thereby lower blood glucose levels (**Figure 8**)(10).

The dependence of glucose-stimulated insulin secretion (GSIS) on cytosolic  $\text{Ca}^{2+}$  activity has been known for more than half a century. Over the past 30 years, however, more and more evidence has accumulated, supporting the notion that not only cytosolic  $\text{Ca}^{2+}$  activity but also its propagation to other cellular organelles are essential for the  $\beta$ -cell to adequately fulfill its function. Especially the mitochondria as central hub connecting oxidative metabolism to insulin secretion have proven to hinge on  $\text{Ca}^{2+}$  in order to maintain and adjust their metabolic function (11). This study focuses on the role of mitochondrial  $\text{Ca}^{2+}$  handling in metabolism-secretion coupling of clonal pancreatic  $\beta$ -cells.

### **1.1 The importance of mitochondria to $\beta$ -cell function**

Electron micrographs have shown that mitochondria are frequently found within close proximity to secretory granules of  $\beta$ -cells (**Figure 1c**) (12). This observation already points to an integral role of this organelle in the process of insulin secretion. However, the study of mitochondrial physiology in pancreatic  $\beta$ -cells is more or less limited to methods that allow the assessment of mitochondrial function in intact cells, since the quantity of  $\beta$ -cell mitochondria that can be isolated from primary islets is comparatively small and potentially contaminated with mitochondria from other islet cells. Yet, recent technical advancements in the field of fluorescent sensors have opened up new possibilities of studying mitochondrial function in one given cell on multiple levels in parallel (13, 14). Such sensors can be used in primary cells, but are particularly applicable in  $\beta$ -cell lines in order to investigate basic concepts in  $\beta$ -cell physiology. Several widely used clonal cell lines have proven to be valuable in overcoming the shortage and limitations of primary  $\beta$ -cells (15, 16) and have helped to study mitochondrial function in this very special type of cell.

The functional integrity of mitochondria is fundamental to  $\beta$ -cell physiology, which is highlighted by the finding that depletion of mitochondrial DNA (mtDNA) causes severe impairment of GSIS in  $\beta$ -cell lines such as MIN6 (17, 18) and INS-1 (19). Certain types of

diabetes are linked to mutations affecting mitochondrial function. Mutations in hepatic nuclear factor 1- $\alpha$ , for example, lead to uncoupling of mitochondrial oxidative phosphorylation (OXPHOS) in INS-1 cells and are associated with type 3 of maturity onset diabetes of the young (MODY3) (20).  $\beta$ -cell-specific knockout of the mitochondrial transcription factor A also causes impaired insulin secretion and loss of  $\beta$ -cell mass resulting in a form of mitochondrial diabetes in mice (21). Mutations in mtDNA have been proposed to account for 0.5 to 1 % of all cases of diabetes in humans (22). Taking into consideration that the majority of all mitochondrial proteins are coded for by nuclear DNA, it can be assumed that the actual prevalence of mitochondrial diabetes is exceeding these estimates. Increasing evidence implicates not only mutations in mtDNA, but also environmental factors such as a surfeit of metabolic substrates and a concomitant increase in reactive oxygen species in the pathogenesis of mitochondrial dysfunction, thus, uncovering the mitochondrion as one of the major culprits in the development of impaired glucose tolerance and diabetes mellitus (23).

The general importance of mitochondrial metabolism to the process of GSIS is reflected by the fact that inhibition of the mitochondrial adenine nucleotide translocase, responsible for transporting ATP out of and ADP into the mitochondrial matrix, completely abolishes glucose-induced electrical activity of  $\beta$ -cells, indicating that glycolysis-derived ATP is not sufficient to maintain proper function (24). Overexpression of the adenine nucleotide translocase in INS-1 cells, however, does not potentiate  $O_2$  consumption rates (OCRs),  $Ca^{2+}$  signals or insulin secretion in response to glucose (unpublished observations), prompting the idea that the transport of ADP/ATP across mitochondrial membranes is not a rate-limiting factor. Inorganic phosphate, which is required by complex V of the electron transport chain to synthesize ATP, is transported into the mitochondria via a phosphate carrier. Silencing of this carrier decreases ATP production and insulin secretion in response to glucose (25). Pharmacological dissipation of the mitochondrial inner membrane potential ( $\Delta\Psi_{mito}$ ) using protonophores, effectively inhibits  $\beta$ -cell secretory activity despite an increase in cytosolic  $Ca^{2+}$  (26), emphasizing the relevance of the spatiotemporal coordination of metabolic and ionic signals. Similar to protonophores, also

overexpression of mitochondrial uncoupling protein 1 (UCP1), which reduces the coupling of OXPHOS, results in decreased ATP production, increased  $K_{ATP}$  channel activity, hyperpolarized plasma membrane potential and drastically impaired GSIS in a mouse  $\beta$ -cell line (27). It is noteworthy, however, that a potentiation of insulin secretion, such as that evoked by glucagon-like peptide-1, is not necessarily associated with an increase in OXPHOS (28) prompting the idea that mitochondrial energy metabolism is essential for insulin secretion, but stimulation of GSIS does not always involve changes in energy metabolism.

**Figure 1. Pancreatic  $\beta$ -cell mitochondria.** **a**, The pancreas contains both exocrine and endocrine cells, the latter of which are distributed throughout the organ forming cell clusters referred to as the pancreatic islets. **b**, Fluorescent micrograph of a mouse islet of Langerhans immunostained for the two primary blood glucose-regulating hormones: insulin (green) and glucagon (red). Nuclei were counterstained with 4',6-diamidino-2-phenylindole (blue). The scale bar represents 20  $\mu$ m. The image was kindly provided by M. Solimena. **c**, Electron micrograph showing part of a pancreatic  $\beta$ -cell. Mitochondria (m) are juxtaposed to insulin-filled secretory granules (sg). The scale bar represents 500 nm. Reprinted from (29).

## 1.2 Mitochondrial integrity and $\beta$ -cell function

Mitochondria constitute an interconnected filamentous network of moving organelles continuously changing their shape through fission and fusion events (30). Dynamics and ultrastructure of this organelle are inseparably linked to its bioenergetic function (31). Fis1, an integral component of the mitochondrial fission machinery, seems to be of particular importance to metabolism-secretion coupling. INS-1E cells overexpressing Fis1 exhibit fragmented mitochondria and fail to hyperpolarize  $\Delta\Psi_{\text{mito}}$  when challenged with high glucose. Interestingly, also mitochondrial  $\text{Ca}^{2+}$  uptake and GSIS were significantly reduced under these conditions (32). In the same study, overexpression of a dominant negative mutant of mitofusin 1 led to similar morphological changes but did not impede GSIS, indicating that changes in mitochondrial structure are not necessarily accompanied by changes on the functional level. These discrepancies might be explained by additional unknown functions of Fis1 or by differential effects on mitochondrial motility. Knockdown of Fis1 resulted in decreased  $\text{O}_2$  consumption and - just like its overexpression - in reduced GSIS (33).

Investigating the function of proteins involved in mitochondrial  $\text{Ca}^{2+}$  sequestration, we have described the fragmentation of mitochondrial networks in  $\beta$ -cells overexpressing MICU1 (34), pointing out the bidirectional relationship between  $\text{Ca}^{2+}$  homeostasis, morphology and motility of mitochondria. The  $\text{Ca}^{2+}$  sensitivity of mitochondrial dynamics is mediated by an EF-hand containing Miro GTPase, which causes mitochondria to halt at sites of high cytosolic  $\text{Ca}^{2+}$  concentrations ( $[\text{Ca}^{2+}]_{\text{cyto}}$ ) (35). It is tempting to speculate that this phenomenon contributes to the fact that  $\beta$ -cell mitochondria regularly localize at subplasmalemmal  $\text{Ca}^{2+}$  hotspots near the readily releasable pool of secretory granules (**Figure 1**) (12) where they might have important functions in controlling local dynamics of  $\text{Ca}^{2+}$ , ATP and other coupling factors (36).

## 1.3 Oxidative metabolism of $\beta$ -cells

The metabolism of the  $\beta$ -cell is quite distinctive as it is directly coupled to the primary cellular function, exceeding the mere task of supplying the cell with energy-rich molecules.

In addition, the  $\beta$ -cell has special preferences when it comes to metabolic substrates. So far a number of substances have been shown to stimulate insulin secretion, the most relevant of these being D-glucose. The branched-chain amino acid leucine and - to a lesser extent - free fatty acids are also amongst the nutrients that evoke insulin secretion. Various hormones and neurotransmitters potentiate insulin secretion via interaction with specific receptors. The main nutrient secretagogues, in contrast, undergo metabolism within the  $\beta$ -cell - more precisely, within its mitochondria - to create second messengers, which then influence  $\beta$ -cell electrical activity and thereby give rise to insulin exocytosis (37).

Metabolic intermediates that serve as source of energy during physical exercise or catabolic states, such as pyruvate, lactate or ketone bodies, need to be ignored by the  $\beta$ -cell in order to avoid hypoglycemic episodes (11). This apparent fuel selectivity requires the cell to express a very specific set of enzymes that make it possible to favor certain substrates, i.e. glucose, over others. In this regard the expression of specific genes has emerged to be just as important as the disallowance of others (38, 39). Loss of the  $\beta$ -cells' ability to discriminate between different substrates has been linked to phenotypes associated with inadequate insulin secretion. In contrast to primary islet cells (40), INS-1 insulinoma cell lines, for example, express significant amounts of the plasma membrane monocarboxylate transporter-1 (MCT1) and thus exhibit robust secretory response also after stimulation with pyruvate (41). A similar phenomenon can be observed in patients manifesting exercise-induced hyperinsulinism, where loss of the  $\beta$ -cell-specific silencing of MCT1 accounts for insulin secretion at times when it is least needed - in response to physical exercise (42). Using a mouse model overexpressing MCT1 in  $\beta$ -cells, it was recently demonstrated that the transport of pyruvate across the plasma membrane is sufficient to induce this form of hyperinsulinism (43).

Being the primary end-product of glycolysis, pyruvate represents a key metabolite in  $\beta$ -cells and not only its oxidation within the mitochondria but also its exchange with tricarboxylic acid (TCA) cycle intermediates have been shown to correlate with glucose responsiveness in different INS-1 cell lines (44). It can hence be assumed that the recently identified mitochondrial pyruvate carrier (45, 46) is essential for intact metabolism-secretion

coupling in  $\beta$ -cells, but its exact role in this context is still awaiting clarification. Once pyruvate has entered the mitochondrial matrix, it can be converted to acetyl-CoA by the pyruvate dehydrogenase (PDH), a protein complex that indirectly depends on free  $\text{Ca}^{2+}$  in its activity, or it can be carboxylated to form oxaloacetate via the pyruvate carboxylase (PC). Either way, pyruvate enters the TCA cycle and thereby fuels the mitochondrial electron transport chain. Lactate dehydrogenase (LDH) is an enzyme that prevents pyruvate from entering oxidative metabolism by converting it into lactate and regenerating  $\text{NAD}^+$  needed during glycolysis. Correspondingly, INS-1 cell clones expressing high levels of LDH fail to accelerate  $\text{O}_2$  consumption rates and insulin secretion in response to high glucose (47). Under normal conditions, NADH generated through glycolysis is efficiently shuttled into the mitochondria where it acts as another glycolysis-derived factor fueling mitochondrial metabolism (48).

Unlike most other cell lines, glucose responsive INS-1 cells have the remarkable ability to further boost their respiratory rate in response to increasing levels of glucose. Strictly speaking this phenomenon can be considered a reverse Crabtree effect: Under high-glucose conditions most clonal (tumor) cell lines tend to reduce OXPHOS to a minimum and solely rely on anaerobic glycolysis in order to meet their energy demands (49). To the  $\beta$ -cell, however, ATP is more than just an energy-rich molecule as its intracellular concentration is coupled to insulin secretion. In order to adjust granule exocytosis to glucose concentrations over a wide dynamic range, ATP synthesis is required to closely reflect glucose supply. If the  $\beta$ -cell would start generating only two molecules of ATP per molecule of glucose instead of the 30 to 32 that can be achieved through OXPHOS (50), the moment glucose levels exceed a certain threshold, it could clearly not keep up with the increasing insulin demand. For this reason  $\beta$ -cells need to increase their OCRs even further under high-glucose conditions. Extracellular glucose concentration relates to the rate of glucose oxidation in a sigmoidal curve with the steepest slope between concentrations of 5.5 and 8 mM of glucose (5) thereby corresponding very well to OCRs, (**Figure 5a**) and GSIS.

There are certain sub-clones of the INS-1 insulinoma cell line, which differ considerably in terms of their secretory response to high glucose. A recent study has linked these differences in metabolism-secretion coupling to the expression levels of genes related to OXPHOS. Any functional defects causing a Warburg-like shift from mitochondrial to anaerobic glycolytic metabolism were found to result in decreased glucose responsiveness of clonal  $\beta$ -cells and also correlate with the severity of a preexisting diabetic phenotype in humans (47). Taken together, these findings highlight the importance of mitochondrial oxidative metabolism in GSIS.

#### **1.4 Mitochondrial coupling factors**

Mitochondria represent the central hub of cellular bioenergetics and are also an organelle with crucial roles in cell signaling (30). In the pancreatic  $\beta$ -cell these two functions overlap in many ways as the mitochondria are the main source not only of ATP but also of a multitude of other signaling molecules, which have been shown to regulate insulin secretion (29).

The amino acid glutamate, for example, is formed from  $\alpha$ -ketoglutarate in  $\beta$ -cell mitochondria during glucose stimulation and has been proposed to act as a mitochondrial signal driving the ATP-independent amplifying phase of insulin secretion (51). Although this concept has been challenged by others using alternative means to increase cytosolic glutamate concentrations (52), measurements of membrane capacitance have revealed a direct effect of glutamate on insulin granule exocytosis (53). Accordingly, disrupting either the generation of glutamate by knocking out glutamate dehydrogenase (54) or its transport out of the mitochondrial matrix by silencing the mitochondrial glutamate carrier (55) impedes GSIS.

Mitochondrial GTP (mtGTP), another potent signaling molecule, forms within the mitochondrion as a byproduct of the TCA cycle in the reaction of succinyl-CoA to succinate and is not exported to the cytosol. Two different isoforms of succinyl-CoA synthetase couple this reaction to the generation of either one molecule of ATP or GTP. Silencing of the ATP-producing isoform resulted in a pronounced increase in GSIS while

knockdown of the GTP-producing form had a negative effect on GSIS (56). Surprisingly, this shift from ATP to mtGTP synthesis was accompanied by a drop in  $\Delta\Psi_{\text{mito}}$ , an increase in  $\text{O}_2$  consumption and a potentiation of cytosolic  $\text{Ca}^{2+}$  activity despite a reduction in ATP. Given that mtGTP-depleted cells showed an increase in overall mitochondrial  $\text{Ca}^{2+}$  concentration ( $[\text{Ca}^{2+}]_{\text{mito}}$ ) after stimulation with glucose, the authors argue that mtGTP might act to promote the extrusion of  $\text{Ca}^{2+}$  from the mitochondria, hence, diverting the proton motive force from ATP production to the electrogenic  $\text{Na}^+/\text{Ca}^{2+}$  exchange. A more recent study implicates mtGTP in controlling mitochondrial production of phosphoenolpyruvate, another factor amplifying GSIS (57). Future work will be needed to elucidate the mechanisms behind mitochondrial GTP-signaling.

Mitochondrial matrix pH, a parameter closely reflecting metabolic activity, naturally correlates very well with nutrient activation in INS-1E cells. Yet, matrix pH seems to affect metabolism-secretion coupling independent of its influence on the electrochemical gradient across the inner mitochondrial membrane (IMM) as proposed by a study using the unspecific  $\text{K}^+/\text{H}^+$  ionophore nigericin to induce matrix acidification (58). Further studies will be needed to identify the molecular mechanisms underlying this phenomenon. Most of these coupling factors are likely to contribute to the feed-forward mechanism elicited by mitochondrial  $\text{Ca}^{2+}$  activity, which contributes mainly to the second phase of insulin secretion (59).

### **1.5 $\text{Ca}^{2+}$ handling in $\beta$ -cells**

Glucose stimulates insulin secretion exclusively in the presence of  $\text{Ca}^{2+}$ , which is illustrated by the fact that hypocalcaemic conditions can impair GSIS (60). Intracellular free  $\text{Ca}^{2+}$  takes central stage in the process of GSIS by directly triggering exocytosis of insulin-filled large dense core vesicles (LDCVs). Several proteins encoded by the synaptotagmin gene family have been implicated in the  $\text{Ca}^{2+}$ -dependency of vesicle membrane fusion (61) while others like syntaxin and synaptosomal protein of 25 kDa seem to be required for tight coupling between voltage-dependent  $\text{Ca}^{2+}$  channels and LDCVs (62). Close physical interaction between local sites of  $\text{Ca}^{2+}$  entry and the exocytotic apparatus is necessary to

guarantee efficient utilization of cytosolic free  $\text{Ca}^{2+}$ , which is limited even during electrical activity of the  $\beta$ -cell. This might be attributable to a comparatively low plasma membrane  $\text{Ca}^{2+}$  channel density (63). Under resting conditions  $[\text{Ca}^{2+}]_{\text{cyto}}$  is kept around 90 nM and even during stimulation overall cytosolic  $\text{Ca}^{2+}$  hardly exceeds concentrations of 400 nM (64). Intracellular application of 10 mM of the  $\text{Ca}^{2+}$ -chelating agent EDTA does not prevent granule exocytosis (65), indicating that the  $\beta$ -cell has apparently developed a very efficient system of cellular  $\text{Ca}^{2+}$  handling to secure both insulin secretion and the transfer of  $\text{Ca}^{2+}$  signals from subplasmalemmal microdomains to cellular compartments such as the mitochondria (66).

### 1.6 Mitochondrial $\text{Ca}^{2+}$ and energy metabolism

A rise of intracellular  $\text{Ca}^{2+}$  is generally associated with cell activation and, thus, with a concomitant increase of cellular energy expenditure. Under these conditions, a vast amount of ATP is utilized within the cell for specific functions such as contraction, ion transport, protein synthesis, motility or exocytosis (67). In order to meet the increased energy demands, most cells are able to accelerate OXPHOS in dependence of cellular  $\text{Ca}^{2+}$  levels and so is the  $\beta$ -cell. Facing rapid, pulsatile changes of  $[\text{Ca}^{2+}]_{\text{cyto}}$  during stimulation with glucose (**Figure 2**), the  $\beta$ -cell can significantly boost both its  $\text{O}_2$  consumption and ATP production rates compared to basal conditions (cf. **Figure 5** and **6**) (59). In the absence of extracellular  $\text{Ca}^{2+}$ , increases in response to glucose are comparatively modest (**Figure 6a**) (59), but still detectable, suggesting that the initial stimulation of mitochondrial metabolism by glucose does not necessarily require extracellular  $\text{Ca}^{2+}$ . The following acceleration of OXPHOS, in contrast, strictly depends on the presence of extracellular  $\text{Ca}^{2+}$ .

Yet, cytosolic  $\text{Ca}^{2+}$  has conflicting effects on mitochondrial metabolism. On the one hand, being a cation, its uptake into the mitochondrial matrix per se causes depolarization of  $\Delta\Psi_{\text{mito}}$ , thereby reducing the driving force for ATP synthesis. In  $\beta$ -cells such transient depolarization occurs shortly after glucose-evoked cytosolic  $\text{Ca}^{2+}$  peaks and can be prevented by removal of extracellular  $\text{Ca}^{2+}$  (68). On the other hand, free  $\text{Ca}^{2+}$  acts as an

activating signal for mitochondrial dehydrogenases, thus providing the electron transport chain with an increasing amount of reducing equivalents (69). Based on mathematical modeling of  $\beta$ -cell  $\text{Ca}^{2+}$  activity, Magnus and Keizer proposed in 1998 that the former would outweigh the latter effect. According to their  $\beta$ -cell model, the glucose-induced uptake of  $\text{Ca}^{2+}$  by mitochondria would cause a drop in  $\Delta\Psi_{\text{mito}}$  in the range of 0.8 mV with slow temporal kinetics, but sufficient to suppress ATP synthesis to an extent that causes opening of  $\text{K}_{\text{ATP}}$  channels, thus implicating mitochondrial  $\text{Ca}^{2+}$  uptake in the termination of electrical bursting in the  $\beta$ -cell (70, 71). This theoretical model, however, is not in line with experimental data from both cell lines and primary  $\beta$ -cells gathered since that time (14, 34, 59).

Despite its pivotal role as a second messenger,  $\text{Ca}^{2+}$  can also be harmful to the cell when its concentration exceeds a threshold over a certain period of time. Apart from the deleterious effects of a persistent elevation of  $[\text{Ca}^{2+}]_{\text{mito}}$  on mitochondrial permeability transition and the initiation of cell death (72), prolonged intracellular  $\text{Ca}^{2+}$  signals observed under maximal stimulation with agonists accelerate mitochondrial metabolism only transiently, whereas oscillations of frequencies  $>0.5/\text{min}$ , as typically seen in stimulated  $\beta$ -cells (cf. **Figure 2**), provoke a sustained activation of  $\text{Ca}^{2+}$ -dependent mitochondrial dehydrogenases (73).

### 1.7 $\text{Ca}^{2+}$ -dependent proteins within the mitochondria

A possible influence of  $\text{Ca}^{2+}$  ions on mitochondrial metabolism was first suggested in the late 1950s and was thereafter confirmed by Denton and McCormack who demonstrated that the activity of three key mitochondrial dehydrogenases is sensitive to  $\text{Ca}^{2+}$  (74). PDH, one of the rate-limiting enzyme complexes of oxidative metabolism, is activated via dephosphorylation by PDH phosphatase, an enzyme highly dependent on the concentration of free  $\text{Ca}^{2+}$  (75). Isocitrate-dehydrogenase and  $\alpha$ -ketoglutarate-dehydrogenase, two TCA cycle enzymes in contrast are regulated by direct binding of  $\text{Ca}^{2+}$  (76, 77). In addition to these, a plethora of other mitochondrial metabolic enzymes have been reported to contain  $\text{Ca}^{2+}$ -binding domains and, thus, represent likely contributors to

the integration of cellular  $\text{Ca}^{2+}$  signals. The EF-hand protein S100A1, for instance, has been shown to activate the ATP synthase itself via  $\text{Ca}^{2+}$ -dependent interaction with its F1 portion (78). The mitochondrial glycerophosphate dehydrogenase (mGDH) is another  $\text{Ca}^{2+}$ -regulated enzyme. As part of the glycerol phosphate shuttle, mGDH is localized to the outer part of the IMM allowing glycolysis-derived NADH to enter oxidative metabolism within the mitochondria (79). It was speculated that an islet specific deficiency in mGDH activity might even contribute to the pathogenesis of type 2 diabetes (80). The mechanisms behind the  $\text{Ca}^{2+}$ -dependent increase of OXPHOS are manifold and involve both direct and indirect actions of  $\text{Ca}^{2+}$  on mitochondrial proteins. This increase of OXPHOS can be observed even beyond the immediate actions of  $\text{Ca}^{2+}$  (81). After pre-stimulation with either high  $\text{K}^+$  or a  $\text{K}_{\text{ATP}}$  channel blocker, MIN-6 cells exhibit an amplified response to glucose when compared to naïve cells (82).

Sound evidence for the activating role of mitochondrial  $\text{Ca}^{2+}$  in  $\beta$ -cells was provided by Wiederkehr and colleagues, who used a  $\text{Ca}^{2+}$ -buffering protein targeted to the mitochondrial matrix to modulate free matrix  $\text{Ca}^{2+}$  and found that buffering of  $[\text{Ca}^{2+}]_{\text{mito}}$  resulted in reduced cellular respiration, ATP production and a decrease in the amplifying phase of insulin secretion (59).

### **1.8 Mitochondrial $\text{Ca}^{2+}$ handling**

Since the early 1960s it is known that respiring mitochondria are able to accumulate significant quantities of  $\text{Ca}^{2+}$  ions (83), but today we are only beginning to understand the molecular basis of this intricate phenomenon. After entering the cytosol,  $\text{Ca}^{2+}$  ions have to permeate both the outer and inner mitochondrial membrane before reaching the mitochondrial matrix. While the outer membrane constitutes less of a burden to ions and molecules smaller than 5 kDa, ion fluxes across the IMM are tightly regulated. So far a number of proteins, comprising ion channels, exchangers and regulatory proteins have been described to contribute to the shuttling of  $\text{Ca}^{2+}$  into and out of the mitochondrial matrix. Putative mitochondrial  $\text{Ca}^{2+}$  channels include the ryanodine receptor 1 (RyR1) (84), uncoupling proteins 2 and 3 (UCP2/3) (85) and the mitochondrial  $\text{Ca}^{2+}$  uniporter

(MCU). MCU is a two transmembrane domain protein of the IMM representing the putative pore-forming subunit of what turns out to be a multi protein MCU-complex (86, 87). Within this complex MCU associates with multiple regulatory proteins, the first of which MICU1 was discovered in 2010 by Mootha and colleagues screening a compendium of IMM proteins (88). MICU1 has one transmembrane domain and two EF-hand motifs on the matrix side that are crucial for its  $\text{Ca}^{2+}$ -sensing properties. More recent studies have suggested MICU1 as a negative regulator of the MCU, preventing mitochondrial  $\text{Ca}^{2+}$  overload under resting conditions (89). MICU2 and MICU3, two additional paralogs of MICU1, have also been identified and might contribute to the tissue specificity of mitochondrial  $\text{Ca}^{2+}$  handling (90). Mitochondrial  $\text{Ca}^{2+}$  uniporter regulator 1 (MCUR1) is another novel regulatory protein that has been reported to act in concert with MCU (91). UCP2/3 have been found particularly important in adjusting mitochondrial  $\text{Ca}^{2+}$  uptake to differences in the concentration (92) and the source (93) of cytosolic  $\text{Ca}^{2+}$ . In contrast to UCP2/3, which preferentially localize at contact sites between the mitochondria and the ER, the mitochondrial  $\text{Ca}^{2+}/\text{H}^+$  antiporter leucine zipper EF-hand-containing protein 1 (LETM1) (94) seems to be responsible for the transfer of  $\text{Ca}^{2+}$  entering the cell through channels in the plasma membrane of endothelial cells (95). Similar differential  $\text{Ca}^{2+}$  uptake mechanisms might have important functions in  $\beta$ -cells, where the extracellular milieu rather than intracellular stores represents the main source of  $\text{Ca}^{2+}$ .

Single channel patch-clamp recordings in mitoplasts isolated from HeLa cells have so far revealed the presence of at least three inwardly rectifying  $\text{Ca}^{2+}$  currents of different amplitudes (96, 97) pointing to the existence of multiple routes of mitochondrial  $\text{Ca}^{2+}$  uptake. To date, studies addressing the putative mitochondrial  $\text{Ca}^{2+}$  uptake pathways in  $\beta$ -cells are still to be carried out. Identification of the molecular machineries responsible for  $\text{Ca}^{2+}$  sequestration by  $\beta$ -cell mitochondria might not only provide better understanding of  $\beta$ -cell physiology but could also help uncover novel therapeutic targets for the treatment of type 2 diabetes.

## 1.9 Aims of the study

This study was designed to assess the function of MICU1 and MCU, two proteins involved in mitochondrial  $\text{Ca}^{2+}$  transport, in clonal pancreatic  $\beta$ -cells and their role in metabolism-secretion coupling.

The specific aims were:

1. To characterize mitochondrial  $\text{Ca}^{2+}$  activities in clonal pancreatic  $\beta$ -cells.
2. To explore the contribution of MICU1 and MCU to mitochondrial  $\text{Ca}^{2+}$  uptake in INS-1 832/13 cells.
3. To determine the effects posttranscriptional gene silencing of MICU1 and MCU on glucose-stimulated  $\text{O}_2$  consumption, ATP production and insulin secretion.

## 2 MATERIALS AND METHODS

### 2.1 Chemicals and buffer solutions

All cell culture products were purchased from PAA Laboratories (Pasching, Austria) unless otherwise specified. Chemicals and reagents were obtained from Carl Roth (Karlsruhe, Germany) or Sigma-Aldrich (Vienna, Austria). All buffer solutions were prepared using ultrapure water from a Milli-Q® Integral Water Purification System (Merck Millipore, Germany). The composition of the buffers was as follows (in mM):

Tris-acetate-EDTA (TAE) buffer: 40 Tris, 20 acetic acid and 1 EDTA.

Hank's buffered salt solution (HBSS): 114 NaCl, 4.7 KCl, 2.5 CaCl<sub>2</sub>, 1.2 MgCl<sub>2</sub>, 2 HEPES, 1.2 KH<sub>2</sub>PO<sub>4</sub>, 25 NaHCO<sub>3</sub> and variable concentrations of D-glucose as indicated, pH adjusted to 7.4 using NaOH.

Pre-incubation buffer (PB): 138 NaCl, 5 KCl, 2 CaCl<sub>2</sub>, 1 MgCl<sub>2</sub>, 1 HEPES, 2.6 NaHCO<sub>3</sub>, 0.44 KH<sub>2</sub>PO<sub>4</sub>, 0.34 Na<sub>2</sub>HPO<sub>4</sub>, 10 D-glucose, 0.1 % vitamins, 0.2 % essential amino acids, and 1 % penicillin/streptomycin, pH adjusted to 7.4 with NaOH.

Experimental buffer (EB): 138 NaCl, 5 KCl, 2 CaCl<sub>2</sub>, 1 MgCl<sub>2</sub>, 10 HEPES and 10 D-glucose, pH adjusted to 7.4 with NaOH. In buffer solutions containing high concentrations of KCl, isoosmolarity was maintained by reducing the concentration of NaCl accordingly.

Phosphate-buffered saline (PBS): 137 NaCl, 2.7 KCl, 10 Na<sub>2</sub>HPO<sub>4</sub>, 1.8 KH<sub>2</sub>PO<sub>4</sub>, pH adjusted to 7.4 with NaOH.

Radioimmunoprecipitation assay (RIPA) buffer: 50 Tris, 150 NaCl, 0.1 % sodium dodecyl sulfate, 0.5 % sodium deoxycholate, 1 % Triton X 100, 5 % protease inhibitor cocktail.

### 2.2 Cell culture

Experiments were carried out using the rat insulinoma cell line INS-1 832/13 stably expressing the human proinsulin gene. These cells exhibit a robust secretory response to glucose which can be attributed to both K<sub>ATP</sub>-dependent and -independent pathways (16). The culture medium used was RPMI-1640 supplemented with 11.1 mM D-glucose, 10 %

fetal calf serum, 2 mM L-glutamine, 1 mM sodium pyruvate, 10 mM HEPES, 100 U/ml penicillin, 100 µg/ml streptomycin and 50 µM β-mercaptoethanol. Cells were cultured in 6-well tissue culture plates at 37 °C gassed with 5 % CO<sub>2</sub> in a humidified atmosphere. For experiments only cells between population doublings 47 and 70 were used.

### **2.3 Islet isolation**

For gene expression analysis, pancreatic islets were isolated from C57/BL6J mice. Mice in between 9 and 12 weeks of age were killed by cervical dislocation and the peritoneal cavity was opened carefully avoiding contamination. Under the stereomicroscope, the common bile duct was identified and ligated as close to the major duodenal papilla as possible using either surgical silk or a small clamp, making sure that the suture is placed distal to the junction with the pancreatic duct (ampulla of Vater). The common bile duct was subsequently cannulated from the proximal side using a 30G needle and a forceps and the pancreas was perfused retrogradely with ~3 ml of HBSS containing 1 mg/ml of collagenase type V (Sigma Aldrich, Austria) until fully distended. In the case of leakage or incomplete distention, the pancreas was microinjected with collagenase solution. The distended pancreas was then removed as a whole, transferred into sterile 15 ml tubes and incubated in a water bath at 37 °C for 12 min after adding another 2 ml of collagenase solution. Digestion was stopped by adding 10 ml of ice cold HBSS containing 0.2 % of BSA. After washing the digested tissue three times with cold HBBS, islets were handpicked under the stereomicroscope, transferred to RPMI-1640 medium supplemented with 5 mM D-glucose and kept in the incubator at 37 °C for up to 24 hours before starting experiments. For measurements of  $[Ca^{2+}]_{cyto}$  an analog procedure was applied to NMRI mice.

### **2.4 Transfection**

Gene knockdown in INS-1 832/13 cells was achieved by transient transfection with a combination of two different siRNAs targeting either rat MICU1 or rat MCU. Transfection with scrambled siRNA was used as a negative control. Sequences of the siRNAs were 5'GUAAUGGAGUAUGAGAAUA and 5'CGAACCUGGUGAAACUGAA for rat MICU1,

5'GCCAGAGACAGACAAUACU and 5'AAAGTCTCGTTTCGACCTA for rat MCU and 5'AGGTAGTGTAATCGCCTTG as a negative control, not targeting any known rat gene. All siRNA sequences were designed by M.R. Alam (98). Cells were cultured in 6-well plates until reaching a confluency of 50-60 % before performing transfection using TransFast™ Transfection Reagent (Promega, USA), a lipofection-based method, according to the manufacturer's recommendations. A transfection mixture containing 200 pmoles/ml of respective siRNAs and/or 3 µg/ml of plasmid DNA as well as 8 µl/ml of TransFast™ Transfection Reagent was prepared in Dulbecco's Modified Eagle Medium (DMEM, Sigma, Austria) free of serum and antibiotics. After vortexing, the mixture was incubated for 15 min at room temperature. The growth medium was removed from 6-well plates and 500 µl/well of transfection mixture were added. Cells were incubated at 37 °C and 5 % CO<sub>2</sub> for 1 hour before replenishing each well with 500 µl of serum and antibiotics-free DMEM. After an incubation period of 18-20 hours, the cells were changed to complete growth medium. All experiments were performed 48-60 hours after transfection.

## **2.5 mRNA quantitation**

### **2.5.1 RNA isolation**

Total cellular RNA was isolated 48 hours after transfection using peqGOLD Total RNA Kit (PEQLAB, Germany) according to the manufacturer's recommendations. Culture medium was removed completely and INS-1 832/13 cells were lysed by adding 200 µl of RNA Lysis Buffer T per well of a 6-well plate, making sure that the surface area is fully submerged to guarantee complete lysis of all cells. The lysate was transferred onto a DNA Removing Column placed in a 1.5 ml reaction tube and centrifuged for 1 min at 12000 g (at room temperature). The flow through was then mixed with 200 µl of ice cold 70 % ethanol (in nuclease free H<sub>2</sub>O) and transferred onto a PerfectBind RNA Column placed in a 2.0 ml collection tube. After 1 min of centrifugation at 10 000 g, the collection tube together with the flow through was discarded. The column was reinserted into a fresh collection tube and 500 µl of RNA Wash Buffer I were added before starting a 15 s centrifugation at 10 000 g. The flow through was discarded and 600 µl of RNA Wash Buffer II (complemented with

ethanol) were added to the column followed by another 15 s of centrifugation at 10 000 g. This second washing step was repeated once. In order to remove any traces of ethanol, the column was centrifuged for another 2 min at 10 000 g. The PerfectBind RNA Column was then transferred to a sterile 1.5 ml reaction tube and total RNA was eluted by adding 20 µl of nuclease-free H<sub>2</sub>O followed by 1 min of centrifugation at 5 000 g. RNA concentration was determined using an UviLine 9400 spectrophotometer (SCHOTT Instruments, Germany). All RNA samples were stored at -70 °C until use.

### **2.5.2 Reverse transcription**

Conversion of RNA into cDNA was achieved using the High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, USA) on a Primus 25 advanced thermocycler (PEQLAB, Germany). The master mix was composed as follows (per 20 µl final reaction volume): 2.0 µl 10X RT Buffer + 2.0 µl 10X Random Primers + 0.8 µl dNTP Mix (100 mM) + 1.0 µl RNasin® Plus RNase inhibitor (Promega, USA) + 1.0 µl nuclease-free H<sub>2</sub>O + 1.0 µl MultiScribe™ Reverse Transcriptase (50 U/µl). As template for cDNA synthesis, total cellular RNA was diluted with nuclease-free H<sub>2</sub>O to a final concentration of 2 µg/10 µl. 10 µl of diluted RNA were added to 10 µl of master mix to create a 1X reaction mix. The thermocycler was programmed to run a 4-step protocol: 25 °C for 10 min, 37 °C for 120 min, 85 °C for 5 min followed by infinite storage at 4 °C.

### **2.5.3 PCR**

In order to verify expression of the respective genes of interest, PCR was performed employing the ready-to-use GoTaq® Green Master Mix (Promega, USA). For a 20 µl-reaction volume, 10 µl of 2X GoTaq® Green Master Mix, 7 µl of nuclease-free H<sub>2</sub>O, 1 µl of upstream primer (10 µM), 1 µl of downstream primer (10 µM) and 1 µl of cDNA template were mixed. Primer sequences were 5'CTGGTGCTGAGTATGTCGTGGA and 5'AGTTGGTGGTGCAGGATGCATT for rat GAPDH (product size: 197 bp), 5'ACTAAGCGGAGACTGATGTTG and 5'GTCCTTGCTCTTCCCCTTATC for rat MICU1 (product size: 149 bp), 5'AGATGGTGTTCGAGTTGCTG and

5'AGGGTCTCTGCGTTTTTCATG for rat MCU (product size: 138 bp), 5'TTGACTTGAATGGAGACGGAG and 5'AACATAAGCCAGACTTGAGGG for mouse MICU1 (product size: 138 bp), and 5'TCGACCTAGAGAAATACAATCAGC and 5'CACGGTCATCTCGGATCATTC for mouse MCU (product size: 137 bp). A Primus 25 advanced thermocycler (PEQLAB, Germany) was deployed to run the following program: 1 cycle of initial denaturation (95 °C for 5 min), 40 cycles of denaturation (95 °C for 1 min), annealing (60 °C for 1 min) and elongation (72 °C for 1 min), 1 cycle of final extension (72 °C for 10 min) and infinite storage at 4 °C.

#### **2.5.4 Gel electrophoresis**

PCR products were visualized by agarose gel electrophoresis. A 1.5 % agarose solution was prepared in TAE buffer using a microwave. 10000X GelRed® Nucleic Acid Gel Stain (Biotium, USA) was added accordingly to create a final concentration of 1X GelRed®. The agarose solution was poured into a casting tray (including a comb) and let solidify. The gel was placed in an electrophoresis chamber filled with TAE buffer. PCR samples and DNA ladder (GeneRuler™ 100 bp, Thermo Fisher Scientific, Austria) were loaded on the gel and run at ~3 V/cm. Bands were visualized using a GenoSmart gel documentation system (VWR International).

#### **2.5.5 Real time PCR**

For relative quantitation of mRNA copies, quantitative real-time PCR was performed using LightCycler® 480 Real-Time PCR System (Roche, Switzerland) and QuantiFast® SYBR Green PCR Kit (Qiagen, Germany). Primer sequences used were the same as listed above and primer efficiencies were determined by analyzing different concentrations of pooled cDNA (1:10, 1:100 and 1:1000). Rat GAPDH was used as a housekeeping gene to normalize for differences in cDNA concentrations between samples. All samples were run in triplicate. Composition of 10 µl of reaction volume: 5 µl of 2X QuantiFast® SYBR Green PCR Master Mix, 1 µl of upstream primer (10 µM), 1 µl of downstream primer (10 µM), 2 µl of nuclease-free H<sub>2</sub>O and 1 µl of cDNA (1:50). Reaction conditions were chosen

according to a standard LightCycler® protocol with an initial heat activation at 95 °C for 5 min followed by 40 cycles of 10 s at 95 °C (denaturation) and 30 s at 60 °C (annealing and extension). The cycle threshold ( $C_T$ ) values were analyzed using the Relative Expression Software Tool (Qiagen, Germany).

## 2.6 $Ca^{2+}$ measurements

### 2.6.1 $[Ca^{2+}]_{cyto}$ measurements in intact islets

Confocal  $Ca^{2+}$  imaging was accomplished as previously described (99). Intact, medium-sized islets from NMRI mice were loaded with 2  $\mu$ M of the  $Ca^{2+}$  indicator Fluo-4 AM (Invitrogen) in RPMI-1640 medium containing 5 mM of D-glucose for 3 hours at room temperature. After loading, islets were transferred to fresh medium without Fluo-4 AM for another 30 min before starting experiments. Laser scanning confocal microscopy was performed using a LSM 510 meta system on an upright microscope (Axioskop 2 FS, Zeiss, Germany) equipped with a micromanipulator. In the perfusion chamber, islets were held in place using a wide-bore holding pipette and perfused throughout the experiment with HBSS containing D-glucose and KCl as indicated. All experiments were conducted at a bath temperature of 35-37 °C. Fluo-4 was excited with an Argon laser at 488 nm, and emission light was captured using a 500-550 nm band-pass filter and a photomultiplier. Fluorescence intensities were normalized to peak values after addition of 30 mM KCl.

### 2.6.2 $[Ca^{2+}]_{mito}$ measurements

INS-1 832/13 cells were cultured on 30 mm glass slides and co-transfected with respective siRNAs and a genetically encoded, FRET-based  $Ca^{2+}$  sensor targeted to the mitochondrial matrix (4mtD3cpv). Measurements were conducted 48-72 hours after transfection on two different microscopy systems, which accounts for the different kinetics of  $[Ca^{2+}]_{mito}$  signals in **Figure 4**. Traces displayed in **Figure 4a** were recorded using an Eclipse TE300 inverted microscope (Nikon, Japan) with a polychromator illumination system (Opti Quip, USA) and a CCD camera (Roper Scientific, Germany). Traces in **Figure 4b** were captured on an Axiovert inverted microscope (Zeiss, Austria) equipped with a polychromator and a CCD

camera (both from Visitron Systems, Germany). 4mtD3cpv was excited at 440 nm and emission was captured at 480 and 535 nm through a 40 x oil-immersion objective (Zeiss and Nikon) using a beam splitter (Visitron Systems). Cells were perfused with EB containing different concentrations of D-glucose as indicated.

### **2.6.3 Simultaneous measurement of $[Ca^{2+}]_{cyto}$ and $[Ca^{2+}]_{mito}$**

Changes in  $[Ca^{2+}]_{cyto}$  and  $[Ca^{2+}]_{mito}$  were recorded simultaneously and ratiometrically on single cell level using a red-shifted cameleon targeted to the mitochondrial matrix in combination with Fura-2 as previously published (13). INS-1 832/13 cells transiently expressing 4mtD1GO-Cam were loaded with 2  $\mu$ M Fura-2 AM in PB for 30 min at room temperature. Before starting experiments, cells were washed 3 times with PB. During measurements, cells were perfused at room temperature with EB containing specified concentrations of D-glucose. Fluorescent images were captured on a digital fluorescence microscope (Till iMIC, Till Photonics, Germany) using a 40 x oil-immersion objective (alpha Plan-Fluor, Zeiss, Germany) with a time interval of 1.5 s to minimize photobleaching. 4mtD1GO-Cam and Fura-2 were excited alternately at 340, 380 (Fura-2) and 477 nm (4mtD1GO-Cam) using a Polychrome V monochromator (Till Photonics, Germany), an excitation filter and a dichroic filter (both Chroma Technology Corp, USA). Emission was detected at 510 nm (Fura-2 and green-channel of 4mtD1GO-Cam) and 560 nm (yellow/FRET-channel of 4mtD1GO-Cam) using an emission filter (Chroma Technology Corp, USA), an additional dichroic filter (Till Photonics, Germany) and a CCD camera (Stingray F145, Allied Vision Technologies, Germany). Original recordings were corrected for photobleaching based on a one-phase exponential decay.

### **2.7 Measurement of cellular O<sub>2</sub> consumption**

INS-1 832/13 cells were plated in XF96 polystyrene cell culture microplates (Seahorse Bioscience, USA) at a density of 50 000 cells per well and transfected with respective siRNAs as depicted above. On the day of the assay, cells were pre-incubated for 1 hour at 37 °C in glucose-free unbuffered XF assay medium (Seahorse Bioscience, USA). Oxygen

consumption rates (OCR) were measured with a time interval of 6 min using an XF96 extracellular flux analyzer (Seahorse Bioscience, USA). FCCP (carbonyl cyanide-4-trifluoromethoxyphenylhydrazone) was injected to determine maximal respiration at a final working concentration of 1  $\mu$ M. Values were normalized to basal respiration.

## 2.8 [ATP]<sub>cyto</sub> measurements

[ATP]<sub>cyto</sub> was assessed by detecting bioluminescence in cells expressing cytosolic firefly luciferase (cLuc), an enzyme catalyzing a light emitting reaction in the presence of ATP and its substrate luciferin. INS-1 832/13 cells were seeded in white-walled 96-well microplates with a clear flat bottom (PerkinElmer Inc., USA) at a density of 70 000 cells/well and co-transfected with respective siRNAs and a plasmid encoding cLuc (kindly provided by Rosario Rizzuto) (36). 48 hours after transfection, the cells were pre-incubated for 1 hour in HBSS containing 0.2 % BSA and 3 mM D-glucose. The buffer was then replaced with HBSS containing 3 mM D-glucose and 1 mM beetle luciferin (Promega, USA). In order to maximize signal-to-noise ratio, the bottom of the plate was covered with a sheet of white paper from beneath before counting emitted photons from the top on a VICTOR Multilabel Reader (PerkinElmer Inc., USA) at 37 °C.

## 2.9 Insulin secretion measurements

INS-1 832/13 cells were cultured in 6-well plates and transfected with respective siRNAs according to the protocol depicted in 2.4 at a confluency of 60-70 %. 48 hours after transfection (at a confluency of 90-100 %), cells were washed two times with warm HBSS and pre-incubated for 1 hour in 2 ml/well HBSS containing 0.2 % BSA and 3 mM D-glucose at 37 °C gassed with 5 % CO<sub>2</sub>. Following pre-incubation, the cells were washed once more and the buffer was replaced by 2 ml HBSS supplemented with 3 mM D-glucose. In order to measure basal insulin secretion, a 1 ml-sample of the supernatant was collected on ice after 60 min of incubation. The remaining supernatant was removed and the respective well was replenished with 2 ml HBSS containing 16 mM D-glucose. After 1 hour of incubation, another sample was collected. The samples were centrifuged for 5 min at

1 800 g and 4 °C to remove any floating cells and 500 µl of the supernatants were collected for further analysis. Insulin concentrations in the supernatants were determined using an enzyme immunoassay (Mercodia Rat Insulin ELISA, Mercodia AB, Sweden) according to the manufacturer's protocol. Samples were analyzed at a 1:10 dilution in calibrator 0. Due to variations in absolute insulin secretion in dependence of the passage number of cells, all values were normalized to basal insulin secretion at 3 mM D-glucose.

### **2.10 Protein quantitation**

Following a brief washing step in cold PBS, cell lysis was performed with RIPA buffer (200 µl/well) and samples were subsequently collected using rubber cell scrapers. Following 3 freeze-thaw cycles in liquid nitrogen, the lysate was centrifuged at 14 000 rpm and 4 °C for 20 min. The supernatant was collected and subjected to protein quantitation employing a bicinchoninic acid assay (Pierce® BCA Protein Assay, Thermo Fisher Scientific Inc., USA). Samples were diluted 1:10 and 10 µl of diluted samples and respective BSA-standards (ranging from 0-2 µg/µl) were pipetted into clear 96-well microplates. After addition of BCA working reagent (150 µl/well), the plate was incubated at 37 °C for ~30 min. Absorbance was measured at 560 nm on a VICTOR<sup>3</sup> V Multilabel Reader (PerkinElmer Inc., USA).

### **2.11 Statistics and data analysis**

Data were analyzed using OriginPro version 8.5.0 (OriginLab Corp., USA) and GraphPad Prism version 5.00 (GraphPad Software, USA) for Windows. Student's t-test or one-way analysis of variance (ANOVA) with Dunnett's post test was performed where appropriate to determine statistical significances. Significance was defined as  $p < 0.05$ . The data are expressed as means  $\pm$  standard error of the mean (SEM) unless otherwise specified.

### 3 RESULTS

#### 3.1 Glucose elicits cytosolic and mitochondrial $\text{Ca}^{2+}$ signals in pancreatic $\beta$ -cells.

In order to characterize cytosolic  $\text{Ca}^{2+}$  signals in different cell types of the pancreatic islet I used the  $\text{Ca}^{2+}$  indicator Fluo-4 to image  $[\text{Ca}^{2+}]_{\text{cyto}}$  in freshly isolated islets from NMRI mice. Glucagon-secreting  $\alpha$ - and insulin-secreting  $\beta$ -cells were distinguished based on their functional characteristics. In both cell types exocytosis is tightly coupled to an increase in  $[\text{Ca}^{2+}]_{\text{cyto}}$ .  $\alpha$ -cells, which release glucagon at low glucose concentrations, show cytosolic  $\text{Ca}^{2+}$ -bursts with a period of  $\sim 5$  min at ambient glucose of  $\leq 6$  mM (**Figure 2a**, black trace).  $\beta$ -cells, however, respond to a step increase in glucose concentration with abrupt initiation of  $[\text{Ca}^{2+}]_{\text{cyto}}$ -oscillations (**Figure 2a**, red trace). Interestingly, certain subpopulations of  $\beta$ -cells within one islet exhibit different threshold glucose concentrations. Only 11 out of 111  $\beta$ -cells (from 9 different islets) responded to 6 mM glucose; however, all 111  $\beta$ -cells responded to glucose concentrations  $\geq 16$  mM with continuous  $[\text{Ca}^{2+}]_{\text{cyto}}$ -oscillations at a frequency of 1-5 peaks/min. To assess in how far such glucose-induced oscillations in  $\beta$ -cell  $[\text{Ca}^{2+}]_{\text{cyto}}$  are transferred to the mitochondrial matrix, I used the clonal INS-1 832/13  $\beta$ -cell line, which, in contrast to primary cells, can be easily transfected with plasmids encoding mitochondrial  $\text{Ca}^{2+}$  sensors such as 4mtD1GO-Cam and thus allow simultaneous measurements of  $[\text{Ca}^{2+}]_{\text{cyto}}$  and  $[\text{Ca}^{2+}]_{\text{mito}}$  (13). This cell line shows sustained secretory response to glucose (16) and also cytosolic  $\text{Ca}^{2+}$  signals are comparable to those of primary  $\beta$ -cells with an oscillation frequency of 0.5-5 peaks/min at 16 mM glucose (**Figure 2b**). Co-imaging of 4mtD1GO-Cam with Fura-2 allowed to examine correlations of  $[\text{Ca}^{2+}]_{\text{mito}}$  and  $[\text{Ca}^{2+}]_{\text{cyto}}$  with highest temporal resolution. Glucose-induced cytosolic  $\text{Ca}^{2+}$  spikes were instantly transferred to the mitochondrial matrix with a time lag of only 3-6 s.  $\text{Ca}^{2+}$  extrusion from  $\beta$ -cell mitochondria, however, displayed significantly slower kinetics compared to respective cytosolic signals (**Figure 2b**, inset). Rapid, repetitive spiking of  $[\text{Ca}^{2+}]_{\text{cyto}}$  led to desensitization of mitochondrial  $\text{Ca}^{2+}$  uptake expressed by the fact that not every single cytosolic  $\text{Ca}^{2+}$  peak was also detectable inside the mitochondria.

**Figure 2. Glucose-induced  $\text{Ca}^{2+}$  signals in pancreatic islets and clonal  $\beta$ -cells.** **a**, Cytosolic  $\text{Ca}^{2+}$  activity measured in a pancreatic  $\alpha$ - (black trace, upper panel) and a juxtaposed  $\beta$ -cell (red trace, lower panel) in one intact pancreatic islet at 3 (3G) and 16 mM glucose (16G) and in response to 30 mM KCl (KCl). Traces are representative of recordings from 46  $\alpha$ - and 111  $\beta$ -cells from 9 different islets. **b**, Correlation of glucose-induced cytosolic and mitochondrial  $\text{Ca}^{2+}$  signals in a clonal INS-1 832/13  $\beta$ -cell. Similar to primary  $\beta$ -cells, stimulation with 16 mM glucose (16G) evoked oscillations of  $[\text{Ca}^{2+}]_{\text{cyto}}$  (red trace). Cytosolic  $\text{Ca}^{2+}$  spikes were followed by respective peaks in mitochondrial  $\text{Ca}^{2+}$  (black dashed trace) with a delay of only 3-6 s.  $\text{Ca}^{2+}$  clearance from the mitochondrial matrix was slower as compared to the cytosolic compartment. The inset is showing a zoom-in image of the marked section.

### 3.2 Expression of MICU1 and MCU in pancreatic $\beta$ -cells

After establishing and characterizing the stimulatory effect of glucose on  $[Ca^{2+}]_{mito}$  in single  $\beta$ -cells, I sought to identify proteins responsible for this cell-specific mode of mitochondrial  $Ca^{2+}$  uptake. Two candidate proteins, MICU1 and MCU have recently been reported to be involved in the uptake of  $Ca^{2+}$  by mitochondria in different mammalian cell lines and tissues (86-88), but their role in  $\beta$ -cells remains enigmatic. Therefore, my aim was

**Figure 3. Expression of MICU1 and MCU in pancreatic  $\beta$ -cells can be reduced by RNAi.** **a**, Agarose gel image confirming the expression of MICU1 and MCU in both isolated mouse islets and INS-1 832/13 cells. GAPDH was used as a positive control. **b**, Quantitative real-time PCR analysis of MICU1 expression in cells treated with scrambled control siRNA (control, n=6) or siRNAs targeted against MICU1 (MICU1 siRNA, n=7) 48 h after transfection. **c**, MCU expression 48 h after transfection with scrambled siRNA (control, n=3) or siRNAs targeting MCU (MCU siRNA, n=6). Bars represent means  $\pm$  SEM; \*\*\*p<0.001.

to investigate the role of these two proteins in pancreatic  $\beta$ -cell function. MICU1 and MCU were detectable at the mRNA level both in primary mouse islets and in the clonal rat  $\beta$ -cell line INS-1 832/13 as confirmed by amplification of cDNA gene fragments using PCR primer pairs specific for the respective genes (for primer sequences see 2.5.3). PCR products were visualized using agarose gel electrophoresis (**Figure 3a**). Confirmation at the protein level was not feasible due to a lack of reliable anti-rat MICU1 (CBARA1) or MCU (CCDC109A) antibodies. Yet, in order to explore the function of MICU1 and MCU, I employed an RNAi-based gene silencing strategy to create cells deficient of the respective proteins, which could subsequently be used in functional assays. To evaluate the efficiency of transient siRNA-mediated knockdown of MICU1 and MCU, quantitative real-time PCR was performed after isolating total RNA from cells transfected with a combination of two specific siRNAs targeting either MICU1 or MCU (for siRNA sequences see 2.4). GAPDH was used as a housekeeping gene to normalize for differences in cDNA content. The number of mRNA copies was expressed relative to that of cells treated with scrambled control siRNA. Treatment with gene-specific siRNAs effectively reduced MICU1 mRNA levels to  $54.0 \pm 5.8$  and MCU mRNA levels to  $65.4 \pm 2.6$  % of control cells (**Figure 3b**).

### 3.3 Glucose-induced mitochondrial $\text{Ca}^{2+}$ uptake is mediated by MICU1 and MCU

Having means to efficiently decrease the expression of MICU1 and MCU in clonal  $\beta$ -cells, I next sought to explore their contribution to the process of mitochondrial  $\text{Ca}^{2+}$  sequestration in this special cell type during stimulation with 16 mM glucose. For this purpose, INS-1 832/13 cells were co-transfected with the mitochondrial  $\text{Ca}^{2+}$  sensor 4mtD3cpv (mito-cameleon) and siRNAs targeting either MICU1 or MCU. 48 hours after transfection, glucose-starved cells were exposed to 16 mM glucose and changes in  $[\text{Ca}^{2+}]_{\text{mito}}$  were recorded as described in 2.6.2. 16 mM glucose triggered pronounced mitochondrial  $\text{Ca}^{2+}$  activities in control cells (**Figure 4a** and **c**, upper panels). In cells treated with siRNAs targeting either MICU1 or MCU, however, these signals were blunted, not to say abolished (**Figure 4a** and **c**, lower panels).

**Figure 4. Knockdown of MICU1 and MCU decreases glucose-induced mitochondrial  $Ca^{2+}$  signals.** Stimulation of INS-1 832/13 cells with 16 mM glucose (16G) elicited spiking of  $[Ca^{2+}]_{mito}$ . **a**, Representative  $[Ca^{2+}]_{mito}$  recordings from cells treated with control (upper panel) and MICU1 siRNA (lower panel). **b**, Total peak area of curves from control (n=122 cells) and MICU1 knockdown cells (n=33 cells) after stimulation with 16G. \*p=0.011. **c**,  $[Ca^{2+}]_{mito}$  traces of control and MCU knockdown (MCU siRNA) cells exposed to high glucose. **d**, Total peak area of recordings from control (n=83 cells) and MCU-silenced cells (n=62 cells) after glucose exposure. Bars represent means  $\pm$  SEM in arbitrary units (AU); \*p=0.013.

Glucose-induced mitochondrial  $\text{Ca}^{2+}$  activities were heterogeneous/dyssynchronous in nature and amplitudes as well as frequencies of oscillations showed considerable variance over time and in between cells, making it difficult to analyze the recorded data quantitatively. To overcome this problem, traces were normalized to initial values and the total peak areas of individual curves were calculated. The total peak area after stimulation with glucose was  $1.49 \pm 0.12$  AU in control and  $0.83 \pm 0.11$  AU in MICU1-silenced cells. Silencing of MCU caused a drop in total peak area from  $1.60 \pm 0.13$  to  $1.17 \pm 0.11$  AU, indicating that both proteins promote glucose-triggered mitochondrial  $\text{Ca}^{2+}$  signals. Based on the observation that knockdown of either protein does not affect global  $[\text{Ca}^{2+}]_{\text{cyto}}$  during glucose-stimulation (98), it can be reasoned that MICU1 and MCU, indeed regulate mitochondrial  $\text{Ca}^{2+}$  transport in clonal  $\beta$ -cells.

#### 3.4 Knockdown of MICU1 affects mitochondrial oxidative metabolism

After confirming that MICU1 and MCU participate in mitochondrial  $\text{Ca}^{2+}$  uptake during glucose-stimulation (see 3.3), I next wanted to explore to which extent MICU1- and MCU-mediated  $\text{Ca}^{2+}$  signals impact OXPHOS, the primary source of ATP in  $\beta$ -cells. Similar to native  $\beta$ -cells, INS-1 832/13 cells are able to boost their respiratory rates in response to glucose with a half maximal effective concentration of 6.2 mM glucose (**Figure 5a**). Maximal respiration as a measure of overall oxidative capacity, can be observed after dissipation of  $\Delta\Psi_{\text{mito}}$  by addition of the protonophore carbonyl cyanide-4-(trifluoromethoxy)phenylhydrazone (FCCP) which showed a sigmoidal dose response curve with a half maximal effective concentration of 173.4 nM (**Figure 5b**). In subsequent experiments all cells were first stimulated with 16 mM glucose before determining maximal  $\text{O}_2$  consumption by treatment with 1  $\mu\text{M}$  FCCP (**Figure 5c**). Control cells increased their OCRs by a peak value of  $22.9 \pm 4.7$  % in response to glucose, whereas cells deficient of MICU1 only showed a moderate increase of  $7.4 \pm 4.5$  %; MCU-silenced cells responded to 16 mM glucose with a maximal increase in OCR of  $16.1 \pm 4.3$  % (**Figure 5c and d**). 24 min after stimulation with glucose,  $\text{O}_2$  consumption in cells deficient of MICU1 or MCU dropped to 98.6 and 108.1 % of basal, respectively. Control cells maintained respiratory

rates as high as 117.8 % of basal even after prolonged exposure to high glucose (**Figure 5c**), indicating that mitochondrial  $\text{Ca}^{2+}$  signals might be especially important for a sustained activation of TCA cycle dehydrogenases during the second (amplifying) phase of GSIS.

**Figure 5. Silencing of MICU1 affects cellular  $\text{O}_2$  consumption.** **a**, INS-1 832/13 cells can increase their oxygen consumption rate (OCR) in response to glucose in a concentration-dependent manner with a half maximal effective concentration ( $\text{EC}_{50}$ ) of 6.2 mM. **b**, Dose response curve for the uncoupling agent FCCP in INS-1 832/13 cells.  $\text{EC}_{50}$ =173.4 nM. **c**, OCRs of INS-1 832/13 cells treated with scrambled siRNA (control, n=20), siRNA targeting MICU1 (MICU1 siRNA, n=21) or MCU (MCU siRNA, n=21). Cells were pre-incubated in glucose-free medium (0G) and stimulated with 16 mM glucose (16G) and 1  $\mu\text{M}$  FCCP at indicated time points. Data were normalized to basal values before stimulation with 16G and are shown as means  $\pm$  SEM. **d**, Maximal OCRs after stimulation with 16G. \* $p$ =0.02, ns: not significant.

FCCP-induced maximal respiration was attenuated by knockdown of MICU1 but remained unchanged by knockdown of MCU. 1  $\mu$ M FCCP provoked maximal OCRs of  $164.1 \pm 8.9$  % in control cells,  $124.0 \pm 7.8$  % in MICU1-deficient and  $153.3 \pm 9.3$  % of basal in MCU-deficient cells (**Figure 5c**), suggesting that  $[Ca^{2+}]_{mito}$  might also affect the overall oxidative capacity of  $\beta$ -cells.

### 3.5 MICU1 and MCU enhance glucose-triggered ATP synthesis

To test whether alterations in oxidative metabolism would also be detectable at the level of cellular ATP production, I measured changes in  $[ATP]_{cyto}$  using INS-1 832/13 cells transiently expressing firefly-derived cLuc. This enzyme catalyzes a chemical reaction emitting photons in the presence of ATP, D-luciferin, Mg and  $O_2$  and can thus be used to estimate subcellular ATP concentrations in a population of cells. In order to test the validity of this method in this particular setting, INS-1 832/13 cells were treated with 16 mM glucose, causing a steady increase in overall  $[ATP]_{cyto}$  with peak values of  $128.0 \pm 3.2$  % of basal (**Figure 6a**, black trace). The same experiment was performed in the presence of the ATP-synthase blocker oligomycin (2  $\mu$ M) in combination with complex III inhibitor antimycin A (10  $\mu$ M) as well as in the absence of extracellular  $Ca^{2+}$ .  $Ca^{2+}$ -free experimental conditions were achieved by addition of 400 nM of the  $Ca^{2+}$  chelator EGTA. Cells treated with ETC inhibitors, known to block ATP synthesis, showed a constant decline in overall  $[ATP]_{cyto}$  (**Figure 6a**, light grey trace). Glucose-treatment in  $Ca^{2+}$ -free buffer caused an increase of only  $14.8 \pm 2.0$  % (**Figure 6a**, grey trace). Taken together, these data indicate that this cLuc-based bioluminescent method provides efficient means to monitor changes in  $[ATP]_{cyto}$  in response to glucose or ETC inhibitors and can also be used to detect alterations in  $[ATP]_{cyto}$  secondary to alterations in  $Ca^{2+}$  signaling. Analog to experiments under  $Ca^{2+}$ -free conditions, cells deficient of MICU1 or MCU also failed to adequately increase  $[ATP]_{cyto}$  in response to 16 mM glucose and showed a mean increase of only  $16.2 \pm 1.5$  % and  $20.3 \pm 1.8$  %, respectively (**Figure 6b**). These results are in line with both measurements of mitochondrial  $Ca^{2+}$  and  $O_2$  consumption in  $\beta$ -cells (cf. **Figure 4** and

5) and point to an integral role of MICU1 and MCU in the decoding of cytosolic  $\text{Ca}^{2+}$  signals inside the mitochondria.

**Figure 6. MICU1 and MCU contribute to the glucose-induced increase in  $[\text{ATP}]_{\text{cyto}}$ .** **a**, INS-1 832/13 cells co-transfected with cLuc and control siRNA were treated with 16 mM glucose in the absence (16G, n=32) and presence of the  $\text{Ca}^{2+}$  chelator EGTA (+EGTA, n=24) or in the presence of 2  $\mu\text{M}$  oligomycin and 10  $\mu\text{M}$  antimycin A (+oligo/AA, n=30). Values were normalized to basal readings at 3 mM glucose (3G). Right panel: Mean  $[\text{ATP}]_{\text{cyto}}$  after stimulation. \*\*\* $p < 0.0001$  vs. 16G. **b**,  $[\text{ATP}]_{\text{cyto}}$  in response to treatment with 16G measured in cells transfected with control siRNA (black, n=32), MICU1 siRNA (light red, n=32) and MCU siRNA (red, n=32). Right panel: Mean values after stimulation with 16G. \*\*\* $p < 0.0001$ , \* $p < 0.05$  vs. control.

### 3.6 MICU1 and MCU are required for sustained insulin secretion

Glucose represents the primary physiological trigger for insulin secretion. According to the consensus model of GSIS, ATP generated through mitochondrial OXPHOS prompts closure of plasma membrane  $K_{ATP}$  channels, depolarizing the cell and thus triggering electrical activity, which involves opening of voltage-dependent  $Ca^{2+}$  channels and causes insulin granule exocytosis (cf. 1.7 and **Figure 8**). After evaluating the effect of MICU1 and MCU knockdown at the levels of  $O_2$  consumption (3.4) and ATP production (3.5), I attempted to explore the role of these two proteins in the principal function of a pancreatic  $\beta$ -cell, namely GSIS. Again, silencing of MICU1 and MCU in INS-1 832/13 cells was achieved by transient transfection with respective siRNAs. In order to exclude any RNAi-mediated unspecific effects on insulin biosynthesis, insulin content was measured in total cell lysates from all experimental groups. Transfection with respective siRNAs did not change cellular insulin content, which was  $7.73 \pm 0.17$  in control,  $7.62 \pm 0.28$  in MICU1-, and  $7.29 \pm 0.35$   $\mu\text{g}/\text{mg}$  protein in MCU-silenced cells (**Figure 7a**). GSIS, however, was drastically affected by knockdown of MICU1 and MCU. Stimulation with 16 mM glucose increased insulin secretion to  $288.0 \pm 17.3$  % of basal levels in control cells. MICU1-deficient cells showed an increase to  $179.5 \pm 9.7$  % and silencing of MCU reduced the effect of 16 mM glucose to  $209.5 \pm 19.6$  % of basal (**Figure 7b**). In agreement with measurements of mitochondrial  $Ca^{2+}$ ,  $O_2$  consumption and cytosolic ATP, these data demonstrate the crucial involvement of MICU1 and MCU in the process of metabolism-secretion coupling in INS-1 832/13 cells.

**Figure 7. Knockdown of MICU1 and MCU impairs glucose-stimulated insulin secretion.** **a**, Total cellular insulin content of cells treated with scrambled control siRNA (n=3) or siRNAs targeting MICU1 (n=3) or MCU (n=3). **b**, Insulin secretion was measured from the supernatants of INS-1 832/13 cells transfected with control siRNA (n=28), MICU1 siRNA (n=22) and MCU siRNA (n=12) after 1 hour of static incubation. GSIS at 16 mM glucose was normalized to basal values at 3 mM glucose. \*\*\*p<0.0001, \*\*p<0.01 vs. control.

## 4 DISCUSSION

The data presented herein define a new mechanistic pathway for the stimulation of  $\beta$ -cell metabolism-secretion coupling by proteins involved in mitochondrial  $\text{Ca}^{2+}$  uptake.  $[\text{Ca}^{2+}]_{\text{mito}}$  is of crucial importance to pancreatic  $\beta$ -cell function, which is to secrete insulin in response to elevated blood glucose. A step increase in extracellular glucose concentration causes an ATP-mediated increase in plasma membrane electrical resistance, depolarizing the cell and thereby triggering electrical activity. L-type  $\text{Ca}^{2+}$  channels, which are rapidly activated during the upstroke of action potentials, account for bulk cytosolic  $\text{Ca}^{2+}$  signals under these conditions (**Figure 2**), while  $\text{Ca}^{2+}$  influx via P/Q-type channels is required for exocytosis (63). A certain subpopulation of mitochondria are believed to be situated close to the inner mouth of L-type, possible also P/Q-type  $\text{Ca}^{2+}$  channels next to secretory granules (**Figure 1**) where they are confronted with oscillations of  $[\text{Ca}^{2+}]_{\text{cyto}}$  at a high frequency. Therefore the  $\beta$ -cell's mitochondria regulate their  $\text{Ca}^{2+}$  uptake differently as compared to other, non-excitabile cell types such as endothelial or HeLa cells (13) and are able to take up  $\text{Ca}^{2+}$  at incredibly high rates as reflected by the steep slope of mitochondrial  $\text{Ca}^{2+}$  increases (**Figure 2b**, black dashed trace) tightly following respective cytosolic spikes (**Figure 2b**, red trace). This instant transfer of cytosolic  $\text{Ca}^{2+}$  oscillations to the mitochondrial matrix has been proposed to activate metabolic enzymes and thereby amplify the production of mitochondrial coupling factors such as ATP (cf. **Figure 8**).

In this context the kinetics of mitochondrial  $\text{Ca}^{2+}$  signals are of special interest; yet, in many cases imaging techniques permit only limited inferences to be drawn about these. Using a recently developed genetically encoded, FRET-based mitochondrial  $\text{Ca}^{2+}$  sensor, it was possible to record mitochondrial and cytosolic  $\text{Ca}^{2+}$  signals in parallel on the single cell level. This approach provides means to study subcellular  $\text{Ca}^{2+}$  handling with unprecedented temporal and spatial resolution while maintaining an excellent signal to noise ratio (**Figure 2**) (13).

In contrast to  $\text{Ca}^{2+}$  influx,  $\text{Ca}^{2+}$  extrusion from  $\beta$ -cell mitochondria displays significantly slower kinetics not only compared to respective cytosolic peaks (**Figure 2b**), but also to other cell types (13), hence allowing for maximal amplification of  $\text{Ca}^{2+}$  signals needed to maintain metabolic activity. However, cytosolic  $\text{Ca}^{2+}$  peaks below a certain threshold are not detectable within the mitochondrial matrix (**Figure 2b**), which might be explainable by different  $\text{Ca}^{2+}$  affinities of channels themselves or of luminal  $\text{Ca}^{2+}$ -sensing subunits such as MICU1. This could also account for the time-dependent desensitization of mitochondrial  $\text{Ca}^{2+}$  sequestration observed during persistent stimulation (**Figure 2b**) (13). Effectively, the mitochondria seem to be able to modify both their  $\text{Ca}^{2+}$  uptake and their  $\text{Ca}^{2+}$  buffering capacity according to the metabolic needs of the cell.

Efflux of  $\text{Ca}^{2+}$  from the mitochondrial matrix is generally accomplished by the mitochondrial  $3 \text{Na}^+/\text{Ca}^{2+} (\text{Li}^+)$  exchanger (NCLX), driven by the inwardly directed electrochemical gradient for  $\text{Na}^+$  (100) and can be inhibited using the benzothiazepine CGP-37157 (101). The idea of blocking the NCLX in order to amplify mitochondrial  $\text{Ca}^{2+}$  signals and thereby also metabolic rates has led to a series of experiments testing the effect of CGP-37157 on pancreatic  $\beta$ -cell function. Initial tests performed in INS-1 cells as well as rats found that treatment with this compound had a positive effect on both ATP production and GSIS in a dose- and glucose-dependent manner (102). Similarly, a more recent study showed that treatment with CGP-37157 is beneficial in restoring ATP levels and GSIS in an in vitro model of mitochondrial diabetes (MODY4) (103). Modulating NCLX activity might, in any case, represent efficient therapeutic means of preserving metabolic function under conditions of mitochondrial deficiency not only in  $\beta$ -cells (104). Based on these observations it can be hypothesized that not only  $\text{Ca}^{2+}$  release from, but also  $\text{Ca}^{2+}$  uptake by mitochondria might play a role in modulating  $\beta$ -cell function.

MICU1 and MCU are two proteins recently described to be implicated in mitochondrial  $\text{Ca}^{2+}$  uptake (86-88). In order to assess their function in clonal pancreatic  $\beta$ -cells and their role in metabolism-secretion coupling I employed an RNAi-based gene silencing strategy to suppress the expression of MICU1 and MCU in INS-1 832/13 cells (**Figure 3**). Silencing of MICU1 and MCU blunted mitochondrial  $\text{Ca}^{2+}$  signals in response to 16 mM glucose

(**Figure 4**) while leaving both frequency and amplitude of cytosolic  $\text{Ca}^{2+}$  oscillations unaffected (34, 98). A combined knockdown of MICU1 and MCU did not result in any additional decrease in mitochondrial  $\text{Ca}^{2+}$  uptake, suggesting that these two proteins are indeed part of the same  $\text{Ca}^{2+}$  uptake pathway (34, 98). Cells deficient of MICU1 also showed a clear reduction in  $\text{O}_2$  consumption after glucose-stimulation as compared to control cells (**Figure 5**). This effect was less pronounced in MCU-deficient cells, probably reflecting variations in gene knockdown efficiency (**Figure 3**) rather than differences in gene function. The efficiency of posttranscriptional gene silencing is crucial when it comes to working with a population of cells and thus not being able to select transfected cells individually. The quantitative analysis of each experiment, however, is reminiscent of the reduction of gene expression achieved by treatment with siRNAs, which was slightly lower for MCU compared to that of MICU1 (**Figure 3**).

In accordance with OCR-measurements, an abrupt rise of extracellular glucose was followed by a progressive increase in  $[\text{ATP}]_{\text{cyto}}$  (**Figure 6**), which was significantly attenuated in MICU1- and to a lesser extent also in MCU-deficient cells. The discrepancy between the effect on  $[\text{ATP}]_{\text{cyto}}$  and GSIS despite a lack of effect on cytosolic  $\text{Ca}^{2+}$  (34, 98) might favor the idea of subplasmalemmal microdomains of high  $[\text{Ca}^{2+}]_{\text{cyto}}$  undetectable by the methods employed in these studies. Expression of a  $\text{Ca}^{2+}$ -buffering protein targeted to the mitochondrial matrix also remained without effect on  $[\text{Ca}^{2+}]_{\text{cyto}}$  (59). Again, this could be explained by the existence of localized  $\text{Ca}^{2+}$  hot spots or by the fact that matrix  $\text{Ca}^{2+}$  modulates GSIS through additional mechanisms that are not directly linked to  $[\text{Ca}^{2+}]_{\text{cyto}}$ . These mechanisms might also include the production of mitochondrial coupling factors other than ATP that are responsible for a sustained amplifying phase of GSIS (cf. **1.4**). A recent report supports the latter hypothesis by ruling out that subplasmalemmal  $\text{Ca}^{2+}$  contributes to the amplifying phase of insulin secretion (105). Tarasov and colleagues, however, recently confirmed the regulatory role of MCU in the glucose-induced generation of ATP (106, 107), which is in agreement with the data presented in **3.5**. In the present study ATP was used as product of OXPHOS and the primary mitochondrial coupling

factor to estimate overall cellular metabolic activity. Other mitochondrial signaling molecules that depend on oxidative metabolism like glutamate or mtGTP (cf. 1.4) were not assessed. Further studies will be needed in order to identify more mitochondrial coupling factors and their specific contribution to the amplifying phase of GSIS.

**Figure 8. Mitochondrial  $Ca^{2+}$  uptake in the pancreatic  $\beta$ -cell.** Glucose taken up by the  $\beta$ -cell via glucose transporter 1 or 2 (GLUT1/2) enters glycolysis to yield pyruvate. Pyruvate is transported into the mitochondrion where it fuels the TCA cycle and thereby oxidative metabolism to generate ATP. ATP in turn causes  $K_{ATP}$  channels ( $K_{ATP}$ ) to close triggering  $Ca^{2+}$  influx via voltage-dependent  $Ca^{2+}$  channels (VDCC).  $Ca^{2+}$  entering the cytosol does not only mediate insulin granule exocytosis, but is also transferred to the mitochondrial matrix in a MICU1- and MCU-dependent manner. Matrix free  $Ca^{2+}$  activates mitochondrial dehydrogenases and thus acts as a feed-forward mechanism boosting mitochondrial  $O_2$  consumption and the production of ATP and possibly other factors required for a sustained amplifying phase of insulin secretion.

In addition to the striking phenotype on the level of cellular metabolism, cells lacking MICU1 or MCU also showed a pronounced reduction in insulin secretion compared to control cells (Figure 7). Coming full circle, Figure 8 pictures how  $Ca^{2+}$  acts at a very late, but also at an early, upstream stage of metabolism-secretion coupling and how MICU1 and MCU contribute to this process.

Considering the fundamental role of mitochondrial  $\text{Ca}^{2+}$  in regulating cellular metabolic activity, the mitochondrial  $\text{Ca}^{2+}$  uptake machinery represents a promising therapeutic target for augmenting insulin secretion in type 2 diabetic patients as well as in those patients suffering from subtypes of diabetes associated with mitochondrial dysfunction. Yet, in view of the fact that MCU is a highly conserved and ubiquitously expressed gene (108), the MCU itself is far from being an ideal drug target. Based on the assumption that mitochondrial  $\text{Ca}^{2+}$  handling is differentially regulated depending on cellular energy status, the source of  $\text{Ca}^{2+}$  (34) as well as the tissue specific expression pattern of regulatory subunits (90), it might nevertheless be possible to selectively manipulate mitochondrial  $\text{Ca}^{2+}$  channels and exchangers in  $\beta$ -cells and thereby potentiate GSIS. In order to make proteins such as MICU1 accessible to specific pharmacological interventions, it will be necessary to precisely characterize their molecular interactions and their exact contribution to metabolism-secretion coupling.
