Statutory declaration

I declare that I have authored this thesis independently, that I have not used other than the declared sources / resources, and that I have explicitly marked all material which has been quoted either literally or by content from the used sources.

Graz, 13th May 2014

Martin Wurm

Acknowledgements

I would like to thank the members of the Ludwig Boltzmann Institute for Lung Vascular Research for all the help and advice they gave to me. The ongoing discussions provided valuable improvements and this work would not have been possible without you. Furthermore, I want to thank Univ. Prof. DDr. Andrea Olschewski and Univ. Prof. Dr. Horst Olschewski for giving me the chance to write my diploma thesis at the LBI and for all the clinical knowledge I was able to learn from you. Also I want to thank Dr. Zoltán Bálint and DI Michael Pienn for introducing me to scientific work and for all the interesting and fun moments I shared with you.

This work would not have been possible without the help of my family, who supported me in every way one could imagine and Judith and Noah, to both I dedicate all the motivation and encouragement.

Abstract

The evaluation of the X-ray attenuation in the lung parenchyma by histogram analysis can give relevant information to quantify pathologic changes in the lung. The main goal of this thesis is to develop an algorithm for lung CT image analysis and to identify diagnostically relevant parameters for pulmonary hypertension (PH) and associated lung diseases, via correlation with patient clinical data. In a clinical CT study of 25 patients we retrospectively applied an automated algorithm to provide statistical information of the lung parenchyma of them. Quantitative readouts of lung parenchyma histograms of patients with and without PH were computed. Statistical analysis has been performed of Hounsfield units and lung perfused blood volume and histograms, skewness, kurtosis, full-width at half-maximum and normalized peak height have been compared. We found specific quantitative parameters of perfused blood volume histograms to differentiate between PH and non-PH patients in our patient cohort.

Kurzfassung

Die Analyse von Histogrammen erstellt aus Computertomographie-Schnittbildern kann wertvolle Anhaltspunkte für pathologische Veränderungen der Lunge liefern. Relevante Informationen im Hinblick auf Lungenhochdruck und ähnlichen Lungenerkrankungen sollten mit den klinischen Daten des Patienten in Verbindung gebracht werden. Es wurde eine Pilotstudie an der 25 Patienten teilnahmen durchgeführt und die Lungenparenchyminformation retrospektiv analysiert und statistisch ausgewertet. Die Lungengefäße wurden isoliert um einen unabhängigen Vergleich zwischen Parenchym, Gefäßen und der gesamten Lunge zu ermöglichen. Die statistische Analyse wurde von Hounsfield units und perfundiertem Lungenblutvolumen durchgeführt, wobei Histogramm, Schiefe, Wölbung, Halbwertsbreite und normalisiertes Maximum von Patienten mit und ohne Lungenhochdruck errechnet wurden. Durch unsere Arbeit konnten wir verschiedene Indikatoren für Lungenhochdruck feststellen. Verschiedene Parameter der Histogrammanalyse von Lungenperfusions-Blutvolumen ermöglichten in unserer Patientenkohorte die Unterscheidung zwischen Lungenhochdruck-Patienten und Patienten ohne Lungenhochdruck.

Chapter 1

Introduction

1.1 General hypothesis

The aim of this study was to improve the diagnostic value of computed tomography (CT) of pulmonary hypertension patients. By means of quantitative analysis of lung CT histograms we aimed to provide relevant diagnostic data for non-invasive detection of lung diseases, especially pulmonary hypertension (PH). Furthermore, without increasing radiation dose for a patient, we wanted to specify signs of pulmonary hypertension. To achieve this goal, we attempted to create an automated algorithm with minimal user intervention for lung CT scan analysis.

1.2 Pulmonary hypertension (PH)

1.2.1 Definition

Pulmonary hypertension (PH) is a severe chronic disease of the lung vasculature and is defined as a mean pulmonary arterial pressure (mPAP) greater than 25 mmHg at rest[30]. There are numerous causes for PH and the pathophysiologic background of most subtypes is not clarified yet. Factors like age and body mass index can also affect mPAP. Healthy patients show mPAP values of 14.0 ± 3.3 mmHg[36], but always below 20 mmHg. Older patients with an increased body mass index often present higher mPAP values, but still below 25 mmHg[46]. The gold standard for diagnosis is the right heart catheterization (RHC), an invasive procedure where the mPAP is measured directly using a probe in the right ventricle and the lung arteries[18]. Resting mPAP of 17 mmHg and above can also lead to reduced survival and adverse events if other diseases are present. This has been shown in several studies on chronic obstructive pulmonary disease (COPD) and lung fibrosis patients[24, 34, 61]. Recent literature also states that although a patients resting mPAP is in a healthy range, exceeding exercise pressure levels can occur[35]. Borderline pulmonary arterial pressure can therefore be a sign for pulmonary vasculopathy. Additionally, other diseases like intrathoracic pressure elevation and left ventricular impairment are a possible cause of this disease[60].

Figure 1.1 – Colored lung vasculature and airways (red = arteries, blue = veins)[65].

1.2.2 WHO classification

According to the most recent WHO classification on pulmonary hypertension from Nice 2013 (5th World Symposium), France, PH is divided to five subgroups[54]:

1. Pulmonary Arterial Hypertension (PAH)
 - 1'. Pulmonary veno-occlusive disease (PVOD) and / or pulmonary capillary hemangiomatosis (PCH)
 - 1''. Persistent pulmonary hypertension of the newborn (PPHN)
2. Pulmonary hypertension owing to left heart disease
3. Pulmonary hypertension owing to left heart disease and / or hypoxia
4. Chronic thromboembolic pulmonary hypertension (CTEPH)
5. Pulmonary hypertension with unclear multifactorial mechanisms

In patients with PAH an increase in pulmonary vascular resistance (PVR) and mean pulmonary arterial pressure (mPAP) can be found[1]. The clinical assessment of a patient suffering from PH can be performed with the WHO classification of the functional status[2].

Updated Clinical Classification of Pulmonary Hypertension (Nice, 2013)	
1.	Pulmonary arterial hypertension (PAH)
1.1.	Idiopathic PAH
1.2.	Heritable PAH
1.2.1.	BMPR2
1.2.2.	ALK-1, ENG, SMAD9, CAV1, KCNK3
1.2.3.	Unknown
1.3.	Drug and toxin induced
1.4.	Associated with:
1.4.1.	Connective tissue diseases
1.4.2.	HIV infection
1.4.3.	Portal hypertension
1.4.4.	Congenital heart diseases
1.4.5.	Schistosomiasis
1'	Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary hemangiomatosis (PCH)
1''	Persistent pulmonary hypertension of the newborn (PPHN)
2.	Pulmonary hypertension due to left heart disease
2.1.	Left ventricular systolic dysfunction
2.2.	Left ventricular diastolic dysfunction
2.3.	Valvular disease
2.4.	Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3.	Pulmonary hypertension due to lung diseases and/or hypoxia
3.1.	Chronic obstructive pulmonary disease
3.2.	Interstitial lung disease
3.3.	Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4.	Sleep-disordered breathing
3.5.	Alveolar hypoventilation disorders
3.6.	Chronic exposure to high altitude
3.7.	Developmental lung diseases
4.	Chronic thromboembolic pulmonary hypertension (CTEPH)
5.	Pulmonary hypertension with unclear multifactorial mechanisms
5.1.	Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
5.2.	Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioliomyomatosis
5.3.	Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4.	Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

Table 1.1 - Updated Clinical Classification of Pulmonary Hypertension (Nice 2013). BMPR = bone morphogenic protein receptor type II; CAV1 = caveolin-1; ENG = endoglin; HIV = human immunodeficiency virus; PAH = pulmonary arterial hypertension[54].

1.2.3 Pathology of pulmonary hypertension

1.2.3.1 Pulmonary arterial hypertension (PAH) and pulmonary veno-occlusive disease (PVOD)

According to the Nice 2013 classification shown above there are different pathological manifestations of the subtypes of PH. In PAH patients mainly the small pulmonary arteries are affected (< 500 μm of diameter). The cell wall shows intimal proliferation, medial hypertrophy and the adventitia becomes thicker. Inflammatory perivascular infiltrations can also be shown in this group. The lung veins are not affected. The pulmonary veno-occlusive disease (PVOD) group shows proliferation of the capillary bed, alveolar haemorrhage and inflammatory infiltrations in the pulmonary veins. The veins also gain a muscular wall. In this disease, pulmonary arteries can be affected, too[18].

Figure 1.2 – Muscularized pulmonary artery from an IPAH patient[16].

1.2.3.2 Pulmonary hypertension owing to left heart disease

Pulmonary hypertension can also be caused by left heart disease and can increase vessel wall thickness, even in pulmonary veins. Other indicators are similar to PAH, for example alveolar haemorrhage and interstitial oedema. In PH due to left heart disease, pulmonary arteries can be affected, too[18].

Figure 1.3 – Representative CT scan of a patient from our PH pilot study, suspect of PH caused by left heart disease.

1.2.3.3 Pulmonary hypertension owing to lung diseases and / or hypoxia

The most common diseases in this group are chronic obstructive pulmonary disease (COPD) and interstitial lung disease (ILD). Pathologic changes are similar to PAH. The distal pulmonary arteries become thicker because of medial hypertrophy and intimal proliferation. The proliferation leads to obstruction of the vessel. Furthermore, in these patients emphysema and fibrosis of the vascular bed can be observed[4][18].

Figure 1.4 – CT scan showing the lung of a patient from our PH pilot study with idiopathic pulmonary fibrosis (IPF).

Figure 1.5 – DE-CT scan with overlay of denoised iodine perfusion CT scan of a patient from our PH pilot study with suspect CTEPH.

1.2.3.4 Chronic thromboembolic pulmonary hypertension (CTEPH)

CTEPH has a different morphology than the other subtypes and presents itself with organised thrombi that are connected to the media of the pulmonary arteries. These thrombi occlude the pulmonary perfusion, leading to the PH symptoms. The vasculature tries to compensate the loss of perfusion in affected areas with enlarged vessels leading to partial reperfusion and overperfusion of non-occluded areas[18].

1.2.3.5 Pulmonary hypertension with unclear multifactorial mechanisms

For this subgroup the pathomechanisms are yet to be clarified. Furthermore the morphology is presented in a very heterogeneous way[18].

1.2.4 Time to diagnosis and outcome

The outcome of the disease may vary depending on the subtype of PH and the severity of the symptoms present. PH is, regardless of progress in recent research, a fatal disease. Without proper treatment, the median survival rate for PAH patients for example is about 2.8 years. Approximately 68% survive the first year, 48% survive three years whereas only 34% are alive after 5 years after diagnosis[41]. A controlled trial of non-treatment is ethically impossible nowadays and the trial I referred to here was performed before the development of a therapy for PH. In a different cohort, patients received epoprostenol as treatment and the survival rates improved to 100% after the first year and 88% after the third year in WHO I or II. Whereas 77% were alive after the first year and 33% after the third year in WHO III, respectively[55]. Obviously a fast and accurate diagnosis of PH is needed to increase survival of patients suffering from PH. There is still a lack of biomarkers that have the power to show the pathologic mechanism, disease severity or treatment response in PH patients. Brain natriuretic peptide and N-terminal fragment of pro-brain natriuretic peptide are mentioned in current guidelines. Additionally, new potential biomarkers are currently investigated. Still there is the need for further research in the identification of promising disease markers[12].

1.2.5 Treatment of PH

The treatment of PH can vary greatly depending on the subgroup of PH diagnosed. Proper therapy slows down clinical worsening and can decrease the symptoms of the patients[21]. Furthermore, mortality can be decreased by 43% and hospitalizations reduced by 61% when comparing patients with therapy to patients with placebo. This has been shown on 23 different randomized controlled trials (RCTs) in PAH patients[19].

Figure 1.6 – Evidence-based treatment algorithm for patients with pulmonary arterial hypertension (for group 1 patients only)[21].

1.2.6 Non-invasive diagnosis of PH

PH is diagnosed by the invasive method of right heart catheterisation (RHC)[18, 54]. Although adverse events of RHC are rare in experienced centers, the development of non-invasive procedures could lead to a further reduction[29] or even replacement of RHC in follow-up examinations[58, 38, 45]. Recent literature shed some light on the possibilities of MRI examinations analysing blood velocity and blood flow patterns in the pulmonary trunk[51, 53]. Additionally, CT became a common procedure to rule out other lung diseases[8, 54]. Cardiac output (CO) is measured by RHC using a method called thermodilution[18, 20, 27]. CO is especially of clinical value because the therapy of the patient and listing for transplantation derives from it. Although there have been numerous evaluations of non-invasive CO determination by inert-gas rebreathing[28, 15, 42], impedance cardiography[62, 13, 47] and echocardiography[62, 44, 11, 14, 50], invasive thermodilution could not be replaced. Promising results have been reported recently by analysing the attenuation-time curves in the pulmonary artery and the ascending aorta from dynamic dual energy computed tomography scans (DECT)[48].

1.3 Computed tomography (CT)

Computed tomography (CT) nowadays has a wide range of diagnostic applications and has become a very valuable tool to differentiate disease types and subtypes. Thoracic CT provides high resolution and high contrast as a minimally invasive technique and is able to identify structural abnormalities in the lung[17]. For pulmonary hypertension patients CT of the chest resembles an important part of the evaluation of the disease[58]. Although the gold standard for diagnosis of PAH is right heart catheterization (RHC), chest CT scans can provide valuable information for ruling out other diseases in the first instance. However, the CT scans contain sufficient information to aid diagnosis of PH[49].

Figure 1.7 – A representative CT scan of a patient from our PH pilot study showing the aorta (Ao) and the dilated main pulmonary artery (PA).

1.3.1 CT for clinical PH diagnosis

When analysing a chest CT scan, there are two major points that give a hint for PAH. The first point is the dilation of the main pulmonary arteries. If they reach a diameter of 29 mm or greater the positive predictive value for PAH is 95% and the specificity is 89%[22]. The second point is the comparison between the diameter of the main pulmonary arteries and the aorta. It has been reported that, whenever the diameter of the main pulmonary arteries becomes greater than the diameter of the aorta, the positive predictive value for PAH is 95% and the specificity is 90%[22]. CT is a key procedure in diagnosis of pulmonary hypertension and is included twice in the diagnostic algorithm of pulmonary hypertension[18]. There is still work to be done to increase the diagnostic relevance of CT in pulmonary hypertension.

Figure 1.8 – Diagnostic Approach to Pulmonary Hypertension. BGA = blood gas analysis, CHD = congenital heart disease, CTD = connective tissue disease, CTEPH = chronic thromboembolic pulmonary hypertension, DLCO = diffusion capacity of the lung for carbon monoxide, ECG = electrocardiogram, HR-CT = high-resolution computed tomography, PA = pulmonary angiography, PAH = pulmonary arterial hypertension, PAPm = mean pulmonary arterial pressure, PAWP = pulmonary arterial wedge pressure, PCH = pulmonary capillary hemangiomatosis, PEA = pulmonary endarterectomy, PFT = pulmonary function testing, PH = pulmonary hypertension, PVOD = pulmonary veno-occlusive disease, PVR = pulmonary vascular resistance, RHC = right heart catheter, RV = right ventricle, V/Q = ventilation/perfusion, x-ray = chest radiograph[30].

1.3.2 Dual-energy computed tomography (DECT)

Dual-energy computed tomography (DECT) operates with two X-ray sources with different acceleration voltages and two detectors working simultaneously and allows the differentiation of tissue because the X-ray attenuation differs according to the tube voltage. This effect is very strong in contrast material such as xenon, barium or iodine. Therefore it is possible to measure iodine concentration on CT images[33]. This method has proven to be very sensitive in the diagnostic process of acute pulmonary embolism or CTEPH[10]. Recent studies also show the possibilities of lung perfused blood volume (PBV) in CTEPH patients by DECT and correlations with RHC parameters[43].

1.4 Objectives

The evaluation of the X-ray attenuation in the lung parenchyma by histogram analysis can give relevant values to quantify pathologic changes in the lung. The main goal is to identify diagnostically relevant parameters for PH and associated lung diseases, via correlation of the CT findings with patient clinical data. Furthermore, we aim to distinguish more common lung diseases like COPD or emphysema from PH in our histogram analysis, as they can show similar morphology in some regions of interest. We attempt to create an automated algorithm that evaluates the CT scan of the lung parenchyma and provides additional information for setting the diagnosis of PH. In the long run, our aim is to create a diagnostic tool with sensitivity and specificity comparable to the gold standard of RHC and therefore reduce the number of RHC a patient needs, especially in follow-up investigations.

Chapter 2

Materials and Methods

2.1 Patient population

The LBI pilot study was approved by the local ethics committee. In the study 25 patients were enrolled and signed informed consent. All of the patients selected for the study already had a RHC for the diagnosis of PH at the Division of Pulmonology between May 2011 and January 2013. Most of the CT examinations were follow-up investigations to identify a change of pathological alterations. Furthermore, all of the CT examinations were done within 3 weeks of the RHC, with a median of 1 day (Table 3.2). There was no change in therapy during this time. Patients with renal failure, pregnancy, a recent diagnostic CT, known adverse reactions to iodinated contrast material and RHC with more than 1 month from the CT examination were excluded from the study.

2.2 Computed tomography (CT)

For the CT examinations a 128-slice dual-energy CT system (Somatom Definition Flash, Siemens, Forchheim, Germany) of the Diagnostikzentrum Graz was used. Patients were instructed to hold their breath in relaxed expiration or breathe slowly and shallowly during acquisition. The gantry rotation time was 0.5 s, the X-ray tubes were set to 100 kV / 53 mAs and 140 kV / 53 mAs with a 0.4 mm tin filter, respectively. 40 ml iodinated contrast material, Ultravist 370 mg/ml iodine (Bayer Schering Pharma Diagnostic Imaging, Leverkusen, Germany), have been injected at 5 ml/s flow rate. A medium-soft kernel (D30f) has been used for reconstruction of the images with 0.6 mm slice thickness. After the CT examination the anonymised data was transferred to an independent workstation.

2.3 Right heart catheterization (RHC)

All patients underwent RHC for follow-up or diagnostic reasons at the Division of Pulmonology, Medical University of Graz. A 7-F quadruple-lumen, balloon-tipped, flow-directed Swan-Ganz catheter (Baxter Healthcare Corp., Irvine, California) was used in a transjugular approach without transparency, performed by the same experienced medical personal.

2.4 Lung Perfused Blood Volume

To increase the discriminative power of our analysis we included perfused blood volume (PBV) data. It is important to mention that the DECT lung PBV data represents a snapshot of the lung perfusion at the given time point when the CT is taken[52]. Therefore it is not equivalent to the perfusion of the lung parenchyma, but it presents the iodine concentration distribution in the parenchyma.[63]

Figure 2.1 – A representative LungPBV scan of a patient from the PH pilot study with CTEPH after pulmonary endarterectomy.

2.5 Histogram analysis

The DECT images have been processed by an algorithm developed at the LBI LVR Graz. For the segmentation and histogram analysis we used MATLAB® R2010b (MathWorks Inc., Massachusetts, USA). In order to achieve an accurate segmentation of the lung parenchyma, the algorithm performed the following steps:

- 3D-segmentation of lung parenchyma
 - Denoising of the CT images and hounsfield units (HU) analysis
 - Isolation of the trachea and exclusion of vessels
 - Gradient calculation to sharpen the edges of lung parenchyma
 - Post-processing of the CT images to avoid segmentation failure and include fibrotic areas / emphysematous lung tissue
- Labeling of the segments found by the algorithm to differentiate left and right lung
- Quantitative analysis of lung parenchyma and lung vessels and visualization of the results

2.6 3D-segmentation of lung parenchyma

2.6.1 Denoising of the CT images and HU analysis

The first step in the development of the algorithm consisted in denoising the image. An automated in-house developed denoising algorithm was used to reduce the impact of noise on the analysis. Furthermore, filtering of the valuable lung parenchyma information had to be achieved. Therefore, a HU-threshold of -970 to -400 was set to exclude bones, fat and liquids, which all present HU at or above zero. As the image could also contain small objects outside of the thorax fulfilling these criteria, the perimeter of the thorax had to be identified to exclude for example the CT examination table from the segmentation. An important approach to achieve this goal was to identify the lung inside the thorax as two black objects, connected via the trachea, and remove all other objects (e.g. remaining noise, examination table) from the image.

2.6.2 Key steps in getting an accurate segmentation

The most important approach to get smooth borders of the lung parenchyma is the 3D ball analysis of the CT scan. All CT images are calculated simultaneously in a 3D array. The key steps of the segmentation consist of several image processing procedures. Dilation increases the border of all voxels in a binary image by a specific amount and geometric structure. In our algorithm we iteratively used balls of different sizes to clear the edges of lung parenchyma and allow the disconnection of the trachea without losing valuable information. The second procedure, called Erosion, works in the opposite direction, removing surrounding voxels of the binary image according to the 3D structure used (Figure 2.2). Again, balls of different sizes are used to delete artifacts in the CT scan. The third important procedure is the Connected Component analysis. With the help of Dilation and Erosion in combination, connected components in the whole CT scan can be identified. This iterative process reduces surroundings of the lung parenchyma, wrongly connected parts and even adds wrongly disconnected parts to the lung parenchyma. The algorithm stops when there are only 2 components left in the CT scan that are not connected to each other. This way identification of the two lungs of the patient is realized (see Figure 2.3).

Figure 2.2 – Image processing procedures: Dilation and Erosion[64].

Figure 2.3 – Left: 3D array of all CT images of a representative CT scan, segmented by 3D balls of different sizes shown as green on the picture. Right: Lung parenchyma segmentation viewed in 3D.

2.6.3 Isolation of the trachea and exclusion of vessels

There have been different approaches to isolate the trachea from the CT scan. One of the steps for our algorithm was to identify the first big object reaching the thorax that is 3-dimensionally connected to the upper border of the image. The trachea was then marked and separated in small steps from the two lung lobes to avoid the loss of parenchyma information. As soon as the trachea lost connection to the two lung lobes, it was removed from the segmentation area. At this point we isolated both lungs with the lung vessels included.

2.6.4 Gradient calculation to sharpen the edges of lung parenchyma

To distinguish the small vessels from the lung parenchyma, it is not accurate enough to just erase the higher HU from the parenchyma, because there would be a loss of lung parenchyma and some vessels would still be present in the image. The later would be caused by darker pixels surrounding the vessel that dampen the brightness of the vessel in the scan. We calculated the gradient of the HU of the pixels in x-, y- and z-direction and removed points in the image whenever the change of the pixels in either x-, y- or z-direction was above a certain level, identifying a vessel path in the lung parenchyma.

2.6.5 Post-processing of the CT images

To avoid segmentation failure and include fibrotic areas / emphysematous lung tissue, more sophisticated approaches had to be developed. We used a region growing algorithm to check whether some parts of the lung were disconnected from the lung parenchyma (for example trapped air hidden behind fibrotic areas). Whenever such areas were found they were included in the lung parenchyma. By using this algorithm, we expected that the level of detail of our analysis will increase, especially in CTEPH patients. On the other hand we had to ensure that emphysematous tissue, represented as very dark areas below our -970 HU threshold, had not been removed. These areas should also yield valuable information, especially in atelectasia and COPD patients. An example of our post-processed segmentation images is shown in Figure 2.4.

Figure 2.4 – CT scan image of a patient, (left) original image, (right) image after segmentation of lung parenchyma. Color coding: dark green = right lung, light green = left lung.

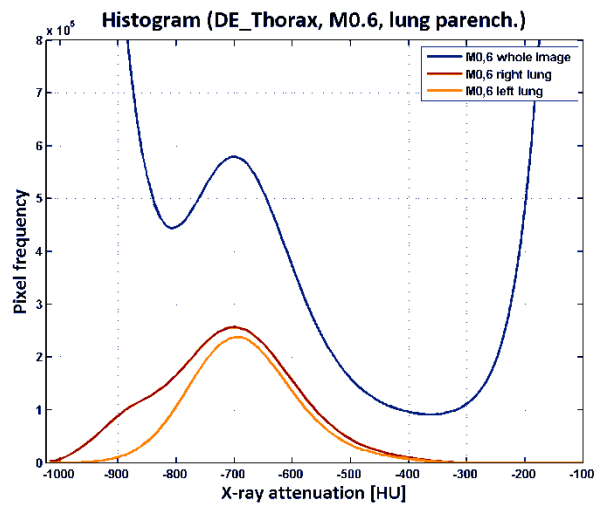

2.7 Quantitative analysis of the CT-scan data

2.7.1 Histogram

Histograms present the distribution of the values of a specific data set and can give a quick impression of how the data is scattered around distinct values. It can be used to visualize the relation between the values, for example the scattering of pixels with different hounsfield units (HU) in a CT image[57]. Two examples are shown on Figure 2.5 where the HU of two patients from the pilot study of the right and left lung can be seen.

A

B

C

D

Figure 2.5 – A: Representative CT image of a patient from our PH pilot study. B: Histogram of the whole CT scan of the corresponding patient. C: Representative CT image of a patient of our PH pilot study. D: Histogram of the whole CT scan of the corresponding patient.

2.7.2 Mean lung attenuation (MLA)

The mean lung attenuation (MLA) \bar{x} is calculated as the attenuation levels in Hounsfield Units (HU) of the lung tissue in the whole scan[4]. It has been shown that this basic histogram parameter correlates with the values of pulmonary function tests (PFTs) in interstitial lung disease (ILD) patients[25].

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n k$$

n ... sample size

k ... value of items

2.7.3 Skewness

The skewness v can describe the asymmetry of a histogram. Skewness is computed with the following formula:

$$v = \frac{1}{n} \sum_{i=1}^n \left(\frac{x_i - \bar{x}}{s} \right)^3$$

n ... sample size

s ... standard deviation

If the skewness is 0, the histogram is perfectly symmetric. A histogram that is skewed to the left has negative skewness values, whereas when skewed to the right the values are positive[37].

2.7.4 Kurtosis

Kurtosis ω is a parameter that provides information about the sharpness of the peak of a histogram. Kurtosis is computed with the following formula:

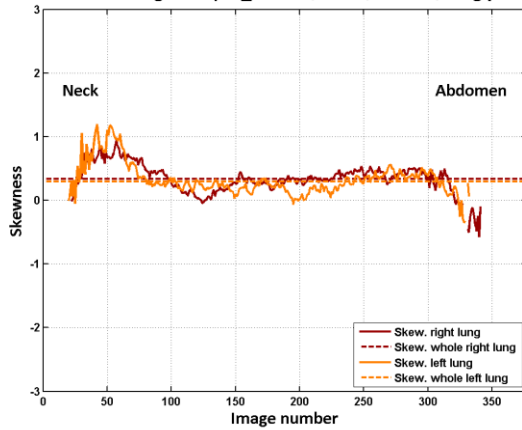

$$\omega = \frac{1}{n} \sum_{i=1}^n \left(\frac{x_i - \bar{x}}{s} \right)^4 - 3$$

n ... sample size

s ... standard deviation

Histograms having the shape of a normal distribution show the kurtosis of 0. A sharper curve has a kurtosis greater than 0, whereas a kurtosis below 0 represents a flatter curve[37].

Skewness of histograms (DE_Thorax, M0.6, transv., lung parench.)

Kurtosis of histograms (DE_Thorax, M0.6, transv., lung parench.)

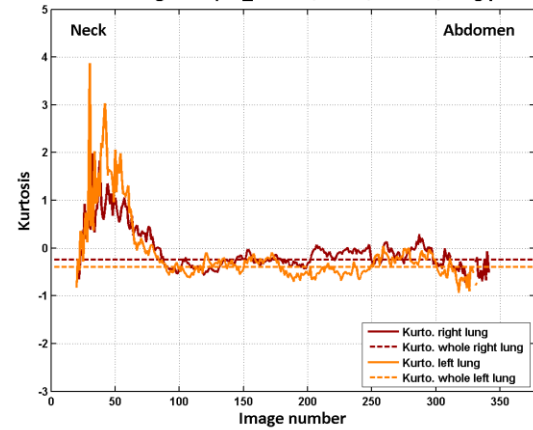

Figure 2.6 – Left: Skewness of a representative Hounsfield unit based CT histogram by image number. Right: Kurtosis of a histogram by image number.

2.7.5 Full-width at half-maximum (FWHM)

The full-width at half maximum (FWHM) can give valuable information about the scattering of the values either side from the peak. Full-width at half-maximum is calculated as follows:

$$FWHM = \frac{1}{s\sqrt{2\pi}} \exp \left[-\frac{(x - \mu)^2}{2s^2} \right]$$

s...standard deviation

2.7.6 Normalized peak height (N_peak)

Because of the different lung sizes of the different patients, the height of the peak was not a valid parameter to analyse. Therefore we normalized the peak height by the sum of all voxels of the specific lung.

$$N_{peak} = \frac{peak_height}{\sum voxels}$$

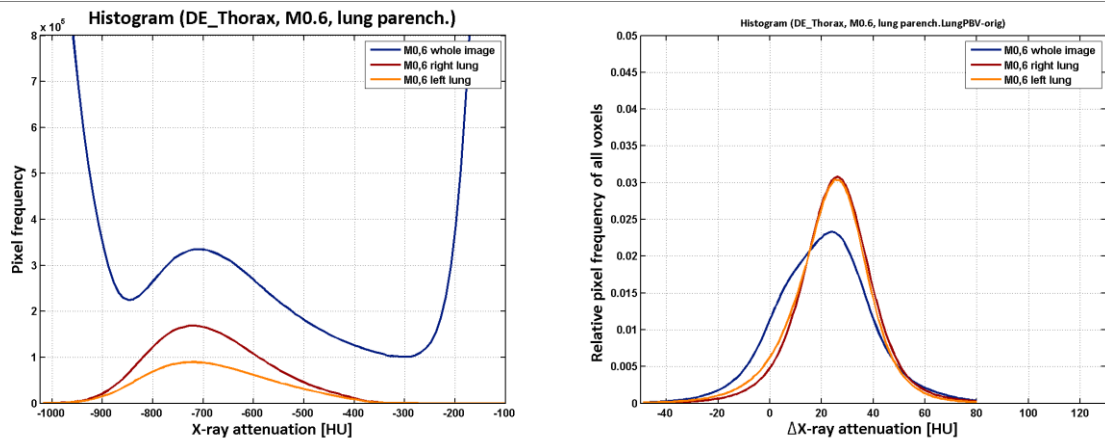

Figure 2.7 – Left: Full-width at half-maximum of a histogram. The FWHM is delineated by the left and right dark and light green dashed lines, respectively. Right: Normalized peak height of a histogram.

2.7.7 Statistical analysis

Statistical analysis was performed in GraphPad Prism (Version 5.04, GraphPad Software, Inc., La Jolla, CA, USA). Correlations between DECT and RHC-derived parameters were calculated using Spearman correlation; differences between PH and non-PH patients were determined using a t-test. We considered P values ≤ 0.05 significant.

Chapter 3

Results

3.1 Patient characteristics

Twenty-five (n=25) patients (female:male = 15:10) were enrolled in a clinical PH pilot study. Four patients had to be excluded from the analysis, three patients (Patient 10, Patient 21, Patient 22) because the data acquisition failed or has not been achieved in 1 month after RHC. One patient had to be excluded because the segmentation algorithm failed to distinguish the two lungs (Patient 19). Therefore the statistical analysis was performed on twenty-one patients.

Patient characteristics	All Patients	No PH	PH
Number of patients	21	5	16
Age [years]	60 ± 14 (27 - 76)	56 ± 7 (50 - 68)	61 ± 16 (27 - 76)
BSA [m ²]	1.9 ± 0.3 (1.5 - 2.7)	1.8 ± 0.1 (1.6 - 1.9)	1.9 ± 0.3 (1.5 - 2.7)
mPAP [mmHg]	37 ± 16 (14 - 66)	16 ± 2 (14 - 19)	44 ± 12 (26 - 66)
PAWP [mmHg]	9 ± 3 (3 - 15)	8 ± 3 (5 - 11)	9 ± 3 (3 - 15)
CO [l/min]	4.5 ± 1.1 (2.9 - 7.8)	5.3 ± 1.5 (4.3 - 7.8)	4.2 ± 0.9 (2.9 - 5.7)
PVR [dyn s cm ⁻⁵]	556 ± 385 (75 - 1416)	112 ± 24 (75 - 131)	695 ± 334 (226 - 1416)
AVDO ₂ [vol%]	4.9 ± 1.0 (2.4 - 6.4)	4.1 ± 0.5 (3.3 - 4.7)	5.2 ± 1.0 (2.4 - 6.4)
art SO ₂ [%]	94 ± 3 (89 - 98)	96 ± 1 (95 - 98)	93 ± 2 (89 - 98)
ven SO ₂ [%]	67 ± 8 (50 - 84)	73 ± 2 (71 - 76)	65 ± 8 (50 - 84)

Table 3.1 – Patient characteristics (BSA = body surface area, mPAP = mean pulmonary arterial pressure, PAWP = pulmonary artery wedge pressure, CO = cardiac output, PVR = pulmonary vascular resistance, AVDO₂ = arteriovenous oxygen difference, artSO₂ = arterial oxygen saturation, venSO₂ = venous oxygen saturation).

3.1.1 Associated diseases

We analysed our patient population based on RHC parameters and clinical diagnosis. Therefore we wanted to investigate underlying diseases.

Patient ID	Indication for RHC	Date of RHC	Indication for CT	Date of CT	Diagnosis
LBI_Pilot01	progressing symptoms	20/06/2011	control of lung fibrosis	21/06/2011	PH - Lung
LBI_Pilot02	planned start of PAH therapy	04/07/2011	exclusion of lung parenchymal disease	05/07/2011	IPAH
LBI_Pilot03	pulmonary endarterectomy	02/10/2011	exclusion of lung parenchymal disease	03/10/2011	CTEPH (after PEA - rest PH)
LBI_Pilot04	pulmonary endarterectomy	07/10/2011	exclusion of lung parenchymal disease	25/10/2011	CTEPH (after PEA - rest PH)
LBI_Pilot05	suspected PH	13/10/2011	suspected progression of scleroderma lung disease	14/10/2011	Scleroderma (no PH)

LBI_Pilot24	suspected PH	04/12/2012	exclusion of lung parenchymal disease	06/12/2012	IPAH
LBI_Pilot25	suspected PH	07/01/2013	exclusion of lung parenchymal disease	08/01/2013	Scleroderma (no PH)

Table 3.2 – Associated diseases of all patients in the clinical PH pilot study (PH = pulmonary hypertension, IPAH = idiopathic pulmonary arterial hypertension, PEA = pulmonary endarterectomy, ILD = interstitial lung disease, OSAS = obstructive sleep apnoea syndrome).

3.1.2 Bolus timing

The CT image acquisition was based on the estimated time for the contrast material bolus injection needed to represent the lung parenchyma best. Bolus timing for the thoracic contrast enhanced CT examination was determined from a dynamic CT sequence carried out prior to the thoracic CT examination. To check whether the bolus timing in our patients was correct, we quantified the average X-ray attenuation in the pulmonary artery and the left atrium and calculated the ratio of AttPA over AttLA (see Table 3.3). Values range between 0.5 and 1.82 resulting in proper performed timing for optimal pulmonary enhancement.

Patient	Att PA [HU]	Att LA [HU]	Ratio
LBI_Pilot01	179	204	0.877
LBI_Pilot02	332	302	1.099
LBI_Pilot03	368	216	1.704
LBI_Pilot04	175	237	0.738
LBI_Pilot05	173	343	0.504
LBI_Pilot06	160	320	0.500
LBI_Pilot07	341	319	1.069
LBI_Pilot08	217	354	0.613
LBI_Pilot09	351	314	1.118
LBI_Pilot10	129	265	0.487
LBI_Pilot11	156	174	0.897
LBI_Pilot12	241	236	1.021
LBI_Pilot13	168	269	0.625
LBI_Pilot14	261	313	0.834
LBI_Pilot15	244	309	0.790
LBI_Pilot16	279	247	1.130
LBI_Pilot17	109	267	0.408
LBI_Pilot18	372	350	1.063
LBI_Pilot19	217	276	0.786
LBI_Pilot20	186	302	0.616
LBI_Pilot21	245	251	0.976
LBI_Pilot23	295	162	1.821
LBI_Pilot24	297	300	0.990
LBI_Pilot25	264	293	0.901

Table 3.3 - Bolus timing (PA = pulmonary artery, LA = left atrium).

3.2 Lung Segmentation

We developed an automatic algorithm to isolate lung parenchyma and lung vessels. This has been achieved in 3D by using thresholds. For lung parenchyma, the HU of -970 to -400 were found sufficient. After the deletion of artifacts from outside of the thorax, the trachea had to be removed from the segmentation. To remove the trachea we used different binary image masks and image processing procedures like erosions and dilations. Furthermore we computed the gradient in x, y and z directions to get clean borders between vessels and parenchyma.

One example of the algorithm is shown on Figure 3.1, where the two separated and identified lungs are depicted (orange = right lung, yellow = left lung).

Figure 3.1 – 3D segmentation of the right lung (orange) and the left lung (yellow) from a representative patient from our PH pilot study.

3.2.1 Advantages

The algorithm we created works fully automatic. There is no user interaction necessary for segmenting lung parenchyma and vessels. Additionally we decided to increase the level of detail of the segmentation by using 3D dependent methods. There are numerous image processing functions in 2D and 3D and it is obvious that by taking the whole CT scan into account to differentiate between parenchyma and surrounding tissue, one can expect more detailed results.

3.2.2 Disadvantages

Although the 3D segmentation process of the lung parenchyma provides a lot of details, the computational effort for this task remains high. At the current status we achieved an average of 20 minutes of processing time for one patient at a standard workstation.

3.2.3 Quality control of segmentation

We performed visual inspection on all CT images having the segmentation as semi-transparent overlay. All patients had satisfying segmentations except Pilot19, which was therefore excluded from the analysis.

3.3 HU histogram analysis

Detailed analysis of all previously mentioned histogram parameters (Section 2.7) has been performed on our datasets. In table 3.4 we represent all individual values for our 6 readouts of the histograms, separated for the left and right lung, respectively.

	Mean		STD		Skew		Kurt		FWHH		N_Peak	
	Left	Right	Left	Right	Left	Right	Left	Right	Left	Right	Left	Right

Table 3.6 – HU histogram Spearman correlations with RHC parameters, right lung.

In the HU histogram analysis significant correlations between all oxygen exchange parameters and FWHM or normalized peak has been found. The individual relations of artSO₂ are depicted on Figure 3.2. Arterial oxygen saturation (art SO₂) had negative correlations with FWHM of $\rho=-0.60$ ($p=0.0034$) and $\rho=-0.59$ ($p=0.004$) of the left and right lung, respectively. Normalized peak values in the left lung had $\rho=0.5835$ ($p=0.0044$) and $\rho=0.5524$ ($p=0.0077$) in the right lung. Venous oxygen saturation (ven SO₂) were correlated with FWHM having $\rho=-0.6375$ ($p=0.0014$) and $\rho=-0.6522$ ($p=0.001$) of the left and right lung, respectively. Normalized peak values in the left lung were correlated with $\rho=0.6228$ ($p=0.002$) in the left lung and $\rho=0.6443$ ($p=0.0012$) in the right lung. No correlations could be observed with body surface area (BSA), age and systemic vascular resistance (SVR). There was also no significant correlation with mPAP or WHO class.

Figure 3.2 – Correlations of HU histogram data with art SO₂.

Lung function parameters also showed linear correlation with quantitative parameters. Total lung capacity (TLC) had linear relation with mean lung attenuation (MLA) of $R^2=0.3886$ ($p=0.01$) and $R^2=0.32$ ($p=0.022$) for left and right lung, respectively. The individual relations are depicted on Figure 3.3.

Table 3.7 – HU histogram data linear regression with lung function parameters.

Figure 3.3 – Correlations of HU histogram data with TLC.

3.3.2 Correlation with image noise

We observed correlation of quantitative parameters with image noise. The results showed significant correlations of mean lung attenuation $\rho=0.53$, skewness $\rho=-0.59$, kurtosis $\rho=-0.50$, full-width at half-maximum $\rho=0.56$ and normalized peak height $\rho=-0.54$ to noise in air. The parameters of the right lung showed similar correlations. All these correlations were driven by 2 outlier values as shown on the individual graphs on Figure 3.4.

Table 3.11 – LungPBV Spearman correlations with RHC parameters, right lung (avgΔAtt = average change in attenuation).

In the LungPBV dataset several correlations could be observed. Body surface area after Dubois (BSA) has shown $\rho=-0.61$ in Spearman correlation with average change in the attenuation. Furthermore, oxygen exchange parameters such as art SO₂ correlated with FWHM ($\rho=-0.53$) and normalized peak ($\rho=0.51$). A correlation of ven SO₂ with FWHM ($\rho=-0.64$) and normalized peak ($\rho=0.62$) was also observed. The parameters of the right lung showed similar correlations. The individual graphs for the correlations with artSO₂ are shown on Figure 3.5.

Figure 3.5 – Correlations of LungPBV data with art SO₂.

3.4.2 Correlations of LungPBV data with image noise

We observed correlation of LungPBV quantitative parameters with image noise. The results showed significant correlations of full-width at half-maximum $\rho=0.78$ and normalized peak height $\rho=-0.79$ to noise in air. Additionally, significant correlations of full-width at half-maximum $\rho=0.54$ and normalized peak height $\rho=-0.56$ to noise in fat have been calculated. The parameters of the right lung showed similar correlations. These correlations were driven by 2 outliers as shown on Figure 3.4.

Table 3.12 – Spearman correlations of LungPBV data with image noise.

3.4.3 Difference between quantitative parameters and WHO class

We observed differences of quantitative parameters of left and right lung between patients in different WHO class. Full-width at half-maximum and normalized peak height, reacting in opposite directions, showed a significant difference between WHO class II and III. WHO class I has only shown 2 patients in our pilot study, therefore this group could not be included in the statistical analysis.

Figure 3.6 – WHO class, LungPBV FWHM and normalized peak height. Center lines indicate the mean, whiskers represent the standard deviation. (* $p < 0.05$)

3.4.4 Differentiation between PH and non-PH patients

The disease group analysis showed a significant difference of average difference in attenuation between patients having PH and those without PH. Our results provided similar values in the left and the right lung (Figure 3.7).

Figure 3.7 – Differentiation between PH and non-PH patients. avg Δ Attenuation = average attenuation difference, PH = pulmonary hypertension. (* p < 0.05)

Figure 3.8 – Values of other histogram parameters.

Although not all parameters showed significant difference with PH diagnosis, a trend can be seen in the performed statistical analyses for increased FWHM and decreased N_peak in PH patients (Figure 3.8).

Chapter 4

Discussion

Firstly, the Hounsfield unit histogram data we calculated in our PH pilot study provide additive information in the diagnostic process of patients suffering from lung diseases. Although the clinical effectiveness of acquiring these values might seem limited, the implementation in daily routine could shorten the time to diagnosis. Quantitative data can give an indication for lung physiology changes based on any thoracic CT of a specific patient and therefore this information can prove valuable and must not be wasted.

Secondly, we performed in-depth analysis of lung perfused blood volume data. This technique requires dual-energy CT which is only available in specific centers. In our analysis we were able to distinguish between patients suffering from PH and those without PH. Preparing the way for non-invasive PH diagnosis, future work should focus on lung perfused blood volume data in a larger cohort to clarify the reliability of this method further.

Automatic lung segmentation is an important tool to get in-depth information of CT images. Especially in DECT images, the acquisition of an accurate lung segmentation can provide valuable disease specific data. However, the computational effort has to find its way in the diagnostic process and therefore has to fulfill several quality criteria. Our approach was to develop a fully automated algorithm without user intervention to minimise the effort needed to include it in daily routine. Furthermore, the computational time has to be in a meaningful range to allow automated lung segmentation and evaluation of quantitative parameters to take its place in diagnostics.

Quantitative analysis has not yet found its place as a novel biomarker in the detection of lung diseases such as pulmonary hypertension. Although recent work shows great potential in detailed quantitative analysis of HRCT in interstitial lung disease patients[3], more work has to be done to validate it as a diagnostic tool. In diffuse lung disease patients distinct histogram shapes has been shown for pathologic structures like ground-glass opacity, reticular opacity, honeycombing, emphysema and airspace consolidation[59]. It has also been shown that quantitative CT analysis bears valuable information about emphysema patterns in smokers[7].

Lung perfused blood volume is a technique provided by Siemens Somatom Definition Flash CT scanners used for representation of contrast agent induced changes in the lung parenchyma. One has to be cautious about possible misunderstanding of this data as they do not show direct perfusion, but rather a snapshot of the iodine distribution at a certain time point[63].

Our work provides a fully automated algorithm for lung segmentation and quantitative analysis of lung CT scans. The results shown have declared the connection to oxygen exchange parameters and the power to

differentiate patients in WHO class II from those in WHO class III. This can be of value in deciding further steps in the diagnostic process. Although oxygen exchange parameters can also be acquired by simple lung function testing, CT has a lot of indications in routine diagnostics and by using this method, can lead the physician to a different diagnostic tool. Most importantly our algorithm was able to differentiate patients having PH from those without PH.

As the awareness of pulmonary hypertension as a possible lung disease is quite low, the time needed to set this diagnosis is about 2 years[31]. Once our results are validated, the opportunity arises to establish a non-invasive diagnostic tool as additional marker for PH. Without the need of an additional, invasive procedure the usually routinely performed CT scan of a patient can be processed and an indication for the presence of pulmonary hypertension can be given. This can in another step lead to a decision of performing right-heart catheterization, gold standard for diagnosing PH, and the definite diagnosis of PH, together with an earlier onset of therapy.

4.1 Limitations

Several limitations of our study have to be mentioned. This has been a pilot study with $n=25$ patients, so our values have to be considered as a proof of concept. In order to validate these results, a prospective study has already achieved ethics approval and is currently running. Furthermore, no CT scans of healthy patients are available. Another limitation of our work is the threshold based parenchyma analysis. The HU of a CT scan can vary depending on tube voltages, body composition and expiration / inspiration level of a patient. Therefore there is still the need to develop an algorithm without taking fixed density values into consideration. Severe emphysematous areas or fibrotic changes of emphysema are hard to detect based on density values, because they can differ greatly from usual lung parenchyma density.

We consider that instead of the HU based histogram analysis one might include/focus on contrast agent based histogram for the determination of lung diseases, especially affecting the pulmonary oxygen exchange and/or perfusion parameters. Although lung perfused blood volume data suffers greatly from image noise, valuable information can be derived from it. There is still need to develop novel denoising techniques to reduce noise influence in these data.

4.2 Outlook

A different approach for lung parenchyma segmentation could be the subsequent dissection of the anatomic structures of the human thorax in the CT image by identifying structures like ribs, the heart or the spine. According to this set points and conditions that can be observed in every CT scan, it should be possible to calculate a lung parenchyma segmentation without using HU thresholds. In a second step it would increase the level of detail of this analysis by calculating lung lobe segmentation. More regional changes will be observable by selecting lung lobes as regions of interest. Additionally, whole lung parenchyma can be analysed by distributing the parenchyma to fixed volumes of interest. These volumes of interest can be analysed separately to increase the level of detail. Furthermore, an automatic trachea isolation algorithm would improve the accuracy of parenchyma detection.

4.3 Conclusion

We created a fully automated algorithm for detailed analysis of CT scans and computed the quantitative values of lung parenchyma in a pilot study. The results we observed show important information of disease parameters in our patient cohort. Our quantitative readouts of the volume histograms have shown correlations with lung function parameters for further clinical relevance. We have shown that lung perfused blood volume histogram normalized peak height and full-width at half-maximum can differentiate between PH and non-PH patients, bearing the potential of a basis for a diagnostic tool as thoracic dual-energy CT.
